## E Additional empirical information and results

### E.1 Sample restrictions

Beginning with the initial sample described in Column (2) of Table 1, I keep paychecks from workers who are paid on a weekly basis, and condition on paychecks that contain a record of positive hours for work, vacation, holidays, or sick leave, totaling fewer than 80 hours in a week.<sup>1</sup> I also drop observations from California, which has a daily overtime rule that is binding for a significant number of workers, and could confound the effects of the weekly FLSA rule.

Furthermore, I focus on hourly workers. While the data include a field for the employer to input a salary, there is no guarantee that employers actually use this feature in the payroll software. Therefore, I use a combination of sampling restrictions to ensure I remove all non-hourly workers from the sample. First, I drop workers that ever have a salary on file with the payroll system. Second, I only keep workers at firms for whom *some* workers have a salary on file, the assumption being that employers either don't use the feature at all or use it for all of their salaried employees. I also drop paychecks from workers for whom hours are recorded as 40 in every week that they appear in the data,<sup>2</sup> as it is possible that these workers are simply coded as working 40 hours despite being paid on a salary basis. I also drop workers who never receive overtime pay.

---

<sup>1</sup>This restriction removes about 2% of the sample after the other restrictions. While a genuine 80 hour workweek is possible, I consider these observations to likely correspond to two weeks of work despite the worker's pay frequency being coded as weekly.

<sup>2</sup>For the purposes of this restriction, I count the "40 hours" event as occurring when either hours of work for pay or total hours of pay (including non-work pay like vacation) is equal to 40.

**Figure 1:** Industry distribution of estimation sample collapsed to the worker level, compared with the CPS sample described in Section 3.

**Figure 2:** Geographical distribution of estimation sample collapsed to the worker level, compared with the CPS sample described in Section 3.

**Figure 3:** Histogram of hours worked pooling all paychecks in sample, with one hour bins, with 40 omitted. Blue mass in the stacks indicate that the paycheck included no overtime pay, while red indicates that the paycheck does include overtime pay. The figure suggests two things: i) compliance with the FLSA overtime mandate is high; and ii) there is little overtime pay voluntarily offered to workers in weeks when they have less than 40 hours of work.

**Figure 4:** Validating the assumption of bi-log-concavity away from the kink, in the case of  $p = 0$ . The left panel plots estimates of  $\ln F_0(h)$  and  $\ln(1 - F_0(h))$  for  $h < 40$ , based on the empirical CDF of observed hours worked. The right panel plots estimates of  $\ln F_1(h)$  and  $\ln(1 - F_1(h))$  for  $h > k$ . Bi-log-concavity requires that the four functions plotted be concave globally. While there is some minor convexity to  $\ln(F)$  for hours close to zero, the log distribution function is approximately linear for all hours close to 40.

Industry	Avg. OT hours	OT % hours	OT % pay	Industry share
Accommodation and Food Services	2.37	0.06	0.11	0.08
Administrative and Support	5.69	0.13	0.18	0.08

**Table 3:** Estimates of the buncher ATE:  $\Delta_k^* = \mathbb{E}[h_{0it} - h_{1it}|h_{it} = k, K_{it}^* = 0]$  based on polynomial extrapolation of quantile functions. 95% bootstrap confidence intervals (in gray) are clustered by firm.

**Figure 6:** Bounds for the bunching that would exist at standard hours  $k$  if it were changed from 40 (left panel), as well as for the impact on average hours (right panel). Bounds of the effect on hours are clipped to the interval  $[-0.5, 0.5]$  for visibility. Pointwise bootstrapped 95% confidence intervals, cluster bootstrapped by firm, are shaded gray.

**Figure 7:** Estimates of the bunching (left panel) and average effect on hours (right panel) were  $k$  changed to any value from 0 to 80, assuming  $p = 0$ . Pointwise bootstrapped 95% confidence intervals, cluster bootstrapped by firm, are shaded gray. Bounds are not informative far from 40. These estimates do not account for adjustment to straight-time wages, so should be viewed as quantifying short-run responses.

The left panel of Figure 6 reports estimates of the identified bounds on  $\mathcal{B}^{[k', \rho_1]}$  as well as point-wise 95% confidence intervals (gray) across values of  $k'$  between 35 and 45, for each of the three approaches to estimating  $p$ . When  $p$  is estimated using PTO or non-changers between periods, the upper bound of the identified set for  $\mathcal{B}^{[k', \rho_1]}$  in fact reaches zero quite quickly in  $k'$ . In all cases, the upper bound on bunching approaches zero as  $k'$  is moved farther from 40. This is sensible if the  $h_0$  and  $h_1$  distributions are roughly unimodal with modes around 40: straddling of potential outcomes becomes less and less likely as one moves away from where most of the mass is. Figure 7 shows these bounds as  $k'$  ranges all the way from 0 to 80, for the  $p = 0$  case. The right panel of Figure 6 shows estimates for the average effect on hours of changing standard hours, inclusive of wage effects (see Appendix J.9 for details). Increases to standard hours cause an increase in hours per worker, as overtime policy becomes less stringent, and reductions to standard hours reduce hours.<sup>3</sup> The size of these effects is not precisely estimated for changes larger than a couple of hours, however the range of statistically significant effects depends on  $p$ .

<sup>3</sup> The magnitudes are consistent with estimates by Costa (2000), that hours fell by 0.2-0.4 on average during the phased introduction of the FLSA in which standard hours declined by 2 hours in 1939 and 1940.

	(1)	(2)	(3)	(4)	(5)
	Work hours=40	OT hours	Total work hours	Work hours=40	OT hours
Tenure	0.000400 (0.95)	0.0515 (3.95)	0.0796 (3.31)

*t* statistics in parentheses

**Table 4:** Columns (1)-(3) regress hours-related outcome variables on worker characteristics, with fixed effects for the date and employer. Standard errors clustered by firm. Columns (4)-(5) show that bunching and overtime hours among incumbent workers are both responsive to new workers being hired within a firm, even controlling for worker and day fixed effects. “Firm just hired” indicates that at least one new worker appears in payroll at the firm this week, and the new workers are dropped from the regression. “Minimum wage worker” indicates that the worker’s straight-time wage is at or below the maximum minimum wage in their state of residence for the quarter. Tenure and age are measured in years, and age is missing for some workers.

### E.3 Estimates imposing the iso-elastic model

This section estimates bounds on  $\epsilon$  from the iso-elastic model described in Section 4.2, under the assumption that the distribution of  $h_{0it} = \eta_{it}^{-\epsilon}$  is bi-log-concave (and linear as in Saez, 2010 as a special case). If  $h_{0it}$  is BLC, bounds on  $\epsilon$  can be deduced from the fact that

$$F_0(40 \cdot 1.5^{-\epsilon}) = F_0(40) + \mathcal{B} = P(h_{it} \leq 40)$$

where  $F_0(h) := P(h_{0it} \leq h)$  and the RHS of the above is observable in the data.  $40 \cdot 1.5^{-\epsilon}$  is the location of this “marginal buncher” in the  $h_0$  distribution. In particular,

$$\epsilon = -\ln(Q_0(F_0(40) + \mathcal{B})/40)/(\ln(1.5))$$

where  $Q_0 := F_0^{-1}$  is guaranteed to exist by BLC (Dümbgen et al., 2017). In particular:

$$\epsilon \in \left[ \frac{\ln \left( 1 - \frac{1-F_0(40)}{40f(40)} \ln \left( 1 - \frac{\mathcal{B}}{1-F_0(40)} \right) \right)}{-\ln(1.5)}, \frac{\ln \left( 1 + \frac{F_0(40)}{40f(40)} \ln \left( 1 + \frac{\mathcal{B}}{F_0(40)} \right) \right)}{-\ln(1.5)} \right]$$

where  $F_0(k) = \lim_{h \uparrow 40} F(h)$  and  $f_0(k) = \lim_{h \uparrow 40} f(h)$  are identified from the data. The bounds on  $\epsilon$  estimated in this way are  $\epsilon \in [-.210, -.167]$  in the full sample, with all bunching  $\mathcal{B}$  attributed to the kink ( $p = 0$ ).

Since BLC is preserved when the random variable is multiplied by a scalar, BLC of  $h_{0it}$  implies BLC of  $h_{1it} := \eta_{it}^{-\epsilon} \cdot 1.5^\epsilon$  as well. This implication can be checked in the data to the

right of 40, since  $\eta_{it}^{-\epsilon} \cdot 1.5^\epsilon$  is observed there. BLC of  $h_{1it}$  implies a second set of bounds on  $\epsilon$ , because:

$$F_1(40 \cdot 1.5^\epsilon) = F_1(40) - \mathcal{B} = P(h_{1it} < 40)$$

and the RHS is again observable in the data, where  $F_1(h) := P(h_{1it} \leq h)$ . Here  $40 \cdot 1.5^\epsilon$  is the location of a second “marginal buncher” – for which  $h_0 = 40$  – in the  $h_1$  distribution. Now we have:

$$\epsilon \in \left[ \frac{\ln \left( 1 + \frac{F_1(40)}{40f_1(40)} \ln \left( 1 - \frac{\mathcal{B}}{F_1(40)} \right) \right)}{\ln(1.5)}, \frac{\ln \left( 1 - \frac{1-F_1(40)}{40f_1(40)} \ln \left( 1 + \frac{\mathcal{B}}{1-F_1(40)} \right) \right)}{\ln(1.5)} \right]$$

where  $F_1(k) = F(k)$  and  $f_1(k) := \lim_{h \downarrow 40} f(h)$  are identified from the data. Empirically, these bounds are estimated as  $\epsilon \in [-.179, -.141]$ . Taking the intersection of these bounds with the range  $\epsilon \in [-.210, -.168]$  estimated previously, we have that  $\epsilon \in [-.179, -.168]$ .<sup>4</sup> The identified set is reduced from a length of .043 to .012, a factor of nearly 4. This underscores the importance of using the data from *both* sides of the kink for identification. Since a linear density satisfies BLC, the identification assumption of Saez, 2010, that the density of  $h_0$  is linear, picks a point within the identified set under BLC. Table 9 verifies that this is born out in estimation (with results are expressed there as level effects rather than an elasticity).

As discussed in Section 4.2, a value for  $\epsilon \approx -.175$  is difficult to reconcile with a realistic view of revenue production with respect to hours. Note that if instead of the isoelastic model, production were instead described by a more general separable and homogeneous production function like

$$\pi_{it}(z, h) = a_{it} \cdot f(h) - z$$

then treatment effects are  $\Delta_{it} = g(1/\eta_{it}) - g(1.5/\eta_{it})$ , where  $g(m) := (f')^{-1}(m)$  yields the hours  $h$  at which  $f'(h) = m$ . We can then use the fundamental theorem of calculus to express this as  $(h_{1it} - h_{0it})/h_{0it} = 1.5^{\bar{\epsilon}_{it}} - 1$  where  $\bar{\epsilon}_{it}$  is a unit-specific weighted average of the inverse elasticity of production between  $1.5\eta_{it}$  and  $\eta_{it}$ :  $\bar{\epsilon}_{it} := \int_{\eta_{it}^{-1}}^{1.5\eta_{it}^{-1}} \lambda(m) \cdot \epsilon(g(m)) \cdot dm$ , and  $\lambda(m) = \frac{1/m}{\ln 1.5}$  is a positive function integrating to one. Here  $\bar{\epsilon}_{it}$  plays the role of an “effective” elasticity parameter that determines the size of treatment effects when the production function is  $f(h)$ . This suggests that simply generalizing the functional form  $f(h)$  is not sufficient to reconcile a realistic picture of production with the data, since the observed bunching still maps to a local average elasticity of  $f(h)$ . However, the general choice model that allows multiple margins of choice  $\mathbf{x}$  can.

---

<sup>4</sup>Note that this interval differs slightly from the identified set of the buncher ATE as elasticity for  $p = 0$  in Table 5. The latter quantity averages the effect in levels over bunchers and rescales:  $\frac{1}{40 \ln(1.5)} \mathbb{E}[h_{0it}(1 - 1.5^\epsilon)|h_{1it} = 40]$ , but the two are approximately equal under  $1.5^\epsilon \approx 1 + .5\epsilon$  and  $\ln(1.5) \approx .5$ .

## E.4 A test of the Trejo (1991) model of straight-time wage adjustment

One way to assess the role of the wage rigidity reported in Table 2 is to test directly whether straight-time wages and hours are plausibly related *at the weekly level* according to Equation (1). Given the kink in Eq. (1), we can perform such a test using the wage and hours reported on each paycheck, while making only weak differentiability assumptions on unobservables for identification.

Suppose that for some subset of units  $it$ , wages are actively adjusted to the hours they work according to Equation (1), in order to target some total earnings  $z_{it}$ . Denote the corresponding units by a latent variable  $A_{it} = 1$ . These units may come from workers with limited variation in their schedules in those weeks in which  $h_{it} = h_i^*$  for some typical hours  $h_i^*$  according to which their wages were set by Eq. (1) at hiring.  $A_{it} = 1$  units might instead have dynamic wages that adjust to week-by-week variation in their hours  $h_{it}$ . Let  $A_{it} = 0$  denote units for whom the worker's wage is determined in some other way. Let  $q(h) = P(A_{it} = 1 | h_{it} = h)$  denote the proportion of these two groups at various points in the hours distribution. An extreme version of the fixed-job model of Trejo (1991) for example, would have  $q(h) = 1$  for all  $h$ .

By the law of iterated expectations and some algebra we have that:

$$\begin{aligned} \mathbb{E} [\ln w_{it} | h_{it} = h] &= q(h) \{ \mathbb{E} [\ln z_{it} | h_{it} = h, A_{it} = 1] - \ln (h + 0.5(h - 40)\mathbb{1}(h \geq 40)) \} \\ &\quad - (1 - q(h)) \mathbb{E} [\ln w_{it} | h_{it} = h, A_{it} = 0] \end{aligned}$$

The middle term above introduces a kink in the conditional expectation of the log of straight-time wages with respect to hours. If we assume that  $\mathbb{E} [\ln z_{it} | h_{it} = h, A_{it} = 1]$ ,  $\mathbb{E} [\ln w_{it} | h_{it} = h, A_{it} = 0]$  and  $q(h)$  are all continuously differentiable in  $h$ , then the magnitude of this kink identifies  $q(40)$ , the proportion of active wage responders local to  $h = 40$ :

$$\lim_{h \downarrow 40} \frac{d}{dh} \mathbb{E} [\ln w_{it} | h_{it} = h] - \lim_{h \uparrow 40} \frac{d}{dh} \mathbb{E} [\ln w_{it} | h_{it} = h] = -\frac{1}{2} \cdot \frac{q(40)}{40}$$

These continuous differentiability assumptions are reasonable, if wage setting according to Equation (1) is the only force introducing non-smoothness in the relationship between wages and hours at 40. For instance, we assume that production technologies do not have any special features at 40 hours that would cause the distribution of target earnings levels  $z_{it}$  among the  $A_{it} = 1$  units to itself have a kink around  $h_{it} = 40$ .

Figure 8 reports the results of fitting separate local linear functions to the CEF of log wages on either side of  $h = 40$ . We can reject the hypothesis that the fixed-job model applies to all employees at all times, near 40. However, the data appear to be consistent with a proportion  $q(40) \approx 0.25$  of all paychecks close to 40 hours reflecting an hours/wage relationship governed by Equation (1). This can be rationalized by straight-wages being

updated intermittently to reflect expected or anticipated hours, which vary in practice quite a bit between pay periods.

**Figure 8:** A test of the fixed-jobs model presented in Trejo (1991), based on the magnitude of the kink in the conditional expectation of log wages with respect to hours at 40 (see above). Regression lines fit on each side with a uniform kernel within 25 hours of the 40. This figure closely resembles Figure 5 of Bick et al. (2022) which uses CPS data for hourly workers.

## E.5 Details of the employment effect calculation

Taking my preferred estimate that hourly workers work approximately  $1/3$  of an hour less per week on average because of the rule, hours per worker are reduced by just under 1%. If we assume the same sized effect occurs for covered salaried workers, and ignore scale effects of the overtime rule on the total number of labor hours in FLSA-eligible jobs, this suggests employment among such jobs is 1% higher than it would be without the overtime premium. This serves as an upper bound, since overall total hours worked may decrease due to overtime regulation.

Following Hamermesh (1993), assume that the percentage change in employment decomposes as:

$$\Delta \ln E|_{EH} - \eta \cdot \Delta \ln LC \cdot \frac{\eta}{\alpha - \eta} \quad (1)$$

where  $\eta$  is constant-output demand elasticity for labor,  $\alpha$  is a labor supply elasticity. Following Hamermesh (1993) I use  $\Delta \ln LC = 0.7\%$  based on Ehrenberg and Schumann (1982), calibrated assuming that 80% of labor costs come from wages with overtime representing 2% of total hours.  $\Delta \ln E|_{EH}$  is the quantity implied by my estimates: the percentage change in employment that would occur were the total number of worker-hours  $EH$  unchanged. Taking a preferred estimate of the average effect of the FLSA as reported in Table 5 to be about  $1/3$  of an hour, I use a value of  $\Delta \ln E|_{EH} = \frac{1/3}{40} \approx 0.9\%$ .

		$\eta$		
		-0.15	-0.3	-0.5
$\alpha$	0	0.76	0.64	0.50
	0.1	0.80	<b>0.70</b>	0.56
	0.5	0.85	0.79	0.68

**Table 11:** Back-of-the-envelope employment effects based on the average reduction in hours estimated via the bunching design and Equation (1), as a function of the demand elasticity for labor (rather than capital)  $\eta$ , and labor supply elasticity  $\alpha$ . The bold entry reflects “best-guess” values of  $\eta$  and  $\alpha$ .

“Best-guess” values for the other parameters used by Hamermesh, 1993 are  $\eta = -0.3$  and  $\alpha = 0.1$ , based on a review of empirical estimates. This yields 0.17 percentage points for the substitution term  $\eta \cdot \Delta \ln LC \cdot \frac{\eta}{\alpha - \eta}$ , suggesting that the effect of the FLSA is attenuated from roughly 0.87 percentage points to about a 0.70 percentage point net increase in employment. I assume that the FLSA overtime rule applies to a total of 100 million workers, based on 80 million hourly workers combined with an estimated 20 million covered salary workers Kimball and Mishel (2015). Assuming the same percentage increase in employment applies to hourly workers and covered salary workers, the above estimate corresponds to 700,000 jobs created. Generating a negative overall employment response by assuming higher substitution to capital requires  $\eta = -1.25$ , well outside of empirical estimates.

## F Incorporating workers that set their own hours

This section considers the robustness of the empirical strategy from Section 4 to a case where some workers are able to choose their own hours. In this case, a simple extension of the model leads to the bounds on the buncher ATE remaining valid, but it is only directly informative about the effects of the FLSA among workers who have their hours chosen by the firm. In this section I follow the notation from the main text where  $h_{it}$  indicate the hours of worker  $i$  in week  $t$ .

Suppose that some workers are able to choose their hours each week without restriction (“worker-choosers”), and that for the remaining workers (“firm-choosers”) their employers set their hours. In general we can allow who chooses hours for a given worker to depend on the period, so let  $W_{it} = 1$  indicate that  $i$  is a worker-chooser in period  $t$ . Additionally, we continue to allow counterfactual bunchers for whom counterfactual hours satisfy  $h_{0it} = h_{1it} = 40$ , regardless of who chooses them. I replace Assumption CONVEX from Section 4 to allow agents to *either* dislike pay (firm-choosers), or like pay (worker-choosers):

**Assumption CONVEX\*** (convex preferences, monotonic in either direction). *For*

each  $i, t$  and function  $B(\mathbf{x})$ , choice is  $(z_{Bi}, \mathbf{x}_{Bi}) = \operatorname{argmax}_{z, \mathbf{x}} \{u_i(z, \mathbf{x}) : z \geq B(\mathbf{x})\}$  where  $u_i(z, \mathbf{x})$  is strictly increasing in  $z$ , if  $W_{it} = 1$ , strictly decreasing in  $z$ , if  $W_{it} = 0$ , and satisfies  $u_i(\theta z + (1 - \theta)z^*, \theta \mathbf{x} + (1 - \theta)\mathbf{x}^*) > \min\{u_i(z, \mathbf{x}), u_i(z^*, \mathbf{x}^*)\}$  for any  $\theta \in (0, 1)$  and points  $(z, \mathbf{x}), (z^*, \mathbf{x}^*)$  such that  $y_i(\mathbf{x}) \neq k$  and  $y_i(\mathbf{x}^*) \neq k$ .

For generality, I here use weaker notion of convexity of preferences from Assumption CONVEX in Appendix B. It is implied by strict quasi-concavity of  $u_i(z, \mathbf{x})$ .

*Note:* This setup is general enough to also allow a stylized bargaining-inspired model in which choices maximize a weighted sum of quasilinear worker and firm utilities. For example, suppose that for any pay schedule  $B(h)$ :

$$h = \operatorname{argmax}_h \beta (f(h) - z) + (1 - \beta)(z - \nu(h)) \quad \text{with} \quad z = B(h) \quad (2)$$

where  $f(h) - z$  is firm profits with concave production  $f$ ,  $z - \nu(h)$  is worker utility with a convex disutility of labor  $\nu(h)$ , and  $\beta \in [0, 1]$  governs the weight of each party in the negotiation (this corresponds to Nash bargaining in which outside options are strictly inferior to all  $h$  for both parties, and utility is log-linear in  $z$ ). Rearranging the maximand of Equation (2) as  $(1 - 2\beta)z + \{\beta f(h) - (1 - \beta)\nu(h)\}$ , we can observe that this setting delivers outcomes as-if chosen by a single agent with quasi-concave preferences, as  $\beta f(h) - (1 - \beta)\nu(h)$  is concave. For Assumption CONVEX from Section 4 to hold with the assumed direction of monotonicity in pay  $z$ , we would require that  $\beta > 1/2$  for all worker-firm pairs: informally, that firms have more say than workers do in determining hours. However the more general CONVEX\* holds regardless of the distribution of  $\beta$  over worker-firm pairs. If  $\beta_{it} < 1/2$ , paycheck  $it$  will look like a worker-chooser, and if  $\beta_{it} > 1/2$  paycheck  $it$  will look like a firm-chooser.

In the generalized model of CONVEX\*, bunching is prima-facie evidence that firm-choosers exist, because there is no prediction of bunching among worker-choosers provided that potential outcomes are continuously distributed. By contrast,  $k$  is a “hole” in the worker-chooser hours distribution: intuitively, if a worker is willing to work 40 hours then they will also find it worthwhile to work more, given the sudden increase in their wage. Indeed under regularity conditions all of the data local to 40 are from firm-choosers (or counterfactual bunchers). To make this claim precise, assume that for worker-choosers, hours are the only margin of response (i.e. their utility depends on  $\mathbf{x}$  only through  $y(\mathbf{x})$ ), and let  $IC_{0it}(y)$  and  $IC_{1it}(y)$  be the worker’s indifference curves passing through  $h_{0it}$  and  $h_{1it}$ , respectively. I assume these indifference curves are twice Lipschitz differentiable, and let  $M_{it} := \sup_y \max\{|IC''_{0it}(y)|, |IC''_{1it}(y)|\}$ , where  $IC''$  indicates second derivatives.

**Proposition F.1.** *Suppose that the joint distribution of  $h_{0it}$  and  $h_{1it}$  admits a continuous density conditional on  $K_{it}^* = 0$ , and that for any worker-chooser  $IC_{0it}$  and  $IC_{1it}$  are differentiable with  $M_{it}/w_{it}$  having bounded support. Then, under CHOICE and CONVEX\*:*

- $P(h_{it} = k \text{ and } K_{it}^* = 0) = P(h_{1it} \leq k \leq h_{0it} \text{ and } K_{it}^* = 0 \text{ and } W_{it} = 0)$
- $\lim_{h \uparrow k} f(h) = P(W_{it} = 0) \lim_{h \uparrow k} f_{0|W=0}(h)$
- $\lim_{h \downarrow k} f(h) = P(W_{it} = 0) \lim_{h \downarrow k} f_{1|W=0}(h)$

*Proof.* See Appendix J. □

The first bullet of Proposition F.1 says that all active bunchers are also firm-choosers, and have potential outcomes that straddle the kink. The second and third bullets state that the density of the data as hours approach 40 from either direction is composed only of worker-choosers. This result on density limits requires the stated regularity condition on  $M_{it}/w_{it}$ , which prevents worker indifference curves from becoming too close to themselves featuring a kink (plus a requirement that straight-time wages  $w_{it}$  be bounded away from zero).

Given the first item in Proposition F.1, the buncher ATE introduced in Section 4 only includes firm-choosers:

$$\mathbb{E}[h_{0it} - h_{1it} | h_{it} = 40, K_{it}^* = 0] = \mathbb{E}[h_{0it} - h_{1it} | h_{it} = 40, K_{it}^* = 0, W_{it} = 0]$$

Accordingly, I assume rank invariance among the firm-chooser population only:

**Assumption RANK\*** (near rank invariance and counterfactual bunchers). *The following are true:*

1.  $P(h_{0it} = k) = P(h_{1it} = k) = p$
2.  $Y_{it} = k$  iff  $(h_{0it} \in [k, k + \Delta_0^*] \text{ and } W_{it} = 0)$  iff  $(h_{1it} \in [k - \Delta_1^*, k] \text{ and } W_{it} = 0)$ , for some  $\Delta_0^*, \Delta_1^*$

where  $p$  continues to denote  $P(K_{it}^* = 1)$ .

We may now state a version of Theorem 2 that conditions all quantities on  $W = 0$ , provided that we assume bi-log concavity of  $h_0$  and  $h_1$  conditional on  $W = 0$  and  $K = 0$ .

**Theorem 1\*** (bi-log-concavity bounds on the buncher ATE, with worker-choosers).

*Assume CHOICE, CONVEX\* and RANK\* hold. If both  $h_{0it}$  and  $h_{1it}$  are bi-log concave conditional on the event  $(W_{it} = 0 \text{ and } K_{it}^* = 0)$ , then:*

$$\mathbb{E}[h_{0it} - h_{1it} | h_{it} = k, K_{it}^* = 0] \in [\Delta_k^L, \Delta_k^U]$$

where

$$\Delta_k^L = g(F_{0|W=0, K^*=0}(k), f_{0|W=0, K^*=0}(k), \mathcal{B}^*) + g(1 - F_{1|W=0, K^*=0}(k), f_{1|W=0, K^*=0}(k), \mathcal{B}^*)$$

and

$$\Delta_k^U = -g(1 - F_{0|W=0, K^*=0}(k), f_{0|W=0, K^*=0}(k), -\mathcal{B}^*) - g(F_{1|W=0, K^*=0}(k), f_{1|W=0, K^*=0}(k), -\mathcal{B}^*)$$

where  $\mathcal{B}^* = P(h_{it} = k | W_{it} = 0, K_{it}^* = 0)$ . The bounds are sharp.

*Proof.* See Appendix J. □

## Identification with worker-choosers

Theorem 1\* does not immediately yield identification of the buncher-ATE bounds  $\Delta_k^L$  and  $\Delta_k^U$ , as we need to estimate each of the arguments to the function  $g$ . As shown in the proof of Theorem 1\*, the bounds can be rewritten in terms of  $p$ , the identified quantities  $\mathcal{B}$ ,  $P(W_{it} = 0) \lim_{y \uparrow k} f_{0|W=0}(y)$  and  $P(W_{it} = 0) \lim_{y \uparrow k} f_{1|W=0}(y)$ , and two unidentified probabilities:  $P(h_{0it} < k \text{ and } h_{it} = h_{0it} \text{ and } W_{it} = 1)$  and  $P(Y_{1it} > k \text{ and } h_{it} = h_{1it} \text{ and } W_{it} = 1)$ .

To illustrate the unidentified quantities, Figure 9 depicts an example of a joint distribution of  $(h_0, h_1)$  that includes worker-choosers and satisfies Assumption RANK\*. The x-axis is  $h_0$ , and the y-axis is  $h_1$ , with the solid lines indicating 40 hours and the dotted diagonal line depicting  $h_1 = h_0$ . The dots show a hypothetical joint-distribution of the potential outcomes, with the (red) dots south of the 45-degree line representing firm-choosers, and the (blue and orange) points above representing worker-choosers. Blue x's indicate worker-choosers who choose their value of  $h_0$ , while orange circles indicate worker-choosers who choose their value of  $h_1$ . The red dot at  $(40, 40)$  represents a mass of counterfactual bunchers.

**Figure 9:** The joint distribution of  $(h_{0it}, h_{1it})$ , for a distribution including worker-choosers and satisfying assumption RANK\*, cf. Figure 5. See text for description.

Observed to the econometrician is the point mass at 40 as well as the truncated marginal distributions depicted at the bottom and the right of the figure, respectively. The observable  $P(h_{it} \leq h)$  for  $h < 40$  doesn't exactly identify  $P(h_{0it} \leq h)$  because some blue x's are missing: these are worker-choosers for whom  $h_1 > 40 > h_0$  and choose to work overtime at their  $h_1$  value. Thus they show up in the data at  $h > 40$  even though they have  $h_0 < 40$ . Similarly, some orange circles do not appear in the observations above 40: these

are worker-choosers for whom  $h_1 > 40 > h_0$  and choose to work their  $h_0$  value, not working overtime. The probabilities  $P(h_{it} < 40 \text{ and } W_{it} = 0)$  and  $P(h_{it} > 40 \text{ and } W_{it} = 0)$  can thus only be estimated with some error, with the size of the error depending on the mass of worker-choosers in the northwest quadrant of Figure 9. However, in practice this has little impact on the results, as the bounds  $\Delta_k^L$  and  $\Delta_k^U$  are not very sensitive to the values of the CDF inputs  $F_{0|W=0, K^*=0}(k)$  and  $F_{1|W=0, K^*=0}(k)$ . The bounds mostly depend on the density estimates and the size of the bunching mass, given their empirical values. Thus Theorem 1\* still partially identifies the buncher LATE among firm-choosers, to a good approximation.

However, a further caveat of Theorem 1\* is worth mentioning. An evaluation of the FLSA would ideally account for worker-choosers (who are working longer hours as a result of the policy) when averaging treatment effects. However, the proportion of worker-choosers and the size of their hours increases are not identified. Using the buncher ATE to estimate the overall ex-post effect of the FLSA—as described in Section 4.4—may overstate its overall average net hours reduction. However, the survey evidence mentioned in Section 2 suggests that the set of worker-choosers is relatively small, mitigating this concern.

## G Interdependencies among hours within the firm

In this section I consider the impact that interdependencies between the hours of different units may have on the estimates, reflected in the third term of Equation (9) from Section 4.4. First, I develop some structure to guide our intuition for this term, and then present some empirical evidence that it is likely to be small (recall that it is taken to be zero in the final results assessing the FLSA).

The basic issue is as follows: when a single firm chooses hours jointly among multiple units—either across different workers or across multiple weeks, or both—this term may be nonzero and contribute to the overall effect of the FLSA. In my potential outcomes notation, this represents a violation of the non-interference condition of the stable unit treatment value assumption (SUTVA), when using the treatment effects  $\Delta_{it}$  to assess the average impact of the FLSA on hours. If firms maximize profits given a production function that is not linearly separable across workers or across weeks, such violations may occur.

To simplify the notation, suppose that SUTVA violations may occur across workers within a firm in a single week, suppressing the time index  $t$  and focusing on a single firm. As in Section 4.4 let  $\mathbf{h}_{-i}$  denote the vector of actual (observed) hours for all workers aside from  $i$  within  $i$ 's firm. These hours are chosen according to the kinked cost schedule introduced by the FLSA. Let  $\mathbf{h}_{0i}(\cdot)$  denote the hours that the firm would choose for worker  $i$  if they had to pay  $i$ ' straight-wage  $w_i$  for all of  $i$ 's hours, as a function of the hours profile of the other workers in the firm (suppressing dependence on straight-wages in this section). Define  $\mathbf{h}_{1i}(\cdot)$  analogously with  $1.5w_i$ . In this notation, the potential outcomes defined in Section 4 are  $h_{0i} = \mathbf{h}_{0i}(\mathbf{h}_{-i})$  and  $h_{1i} = \mathbf{h}_{1i}(\mathbf{h}_{-i})$ . As in Section 4.4 let  $(h_i^*, \mathbf{h}_{-i}^*)$  denote the hours

profile that would occur absent the FLSA, so that the average ex-post effect of the FLSA is  $\mathbb{E}[h_i - h_i^*]$ .

Even if there are SUTVA violations, treatment effects  $\Delta_i = \mathbf{h}_{0i}(\mathbf{h}_{-i}) - \mathbf{h}_{1i}(\mathbf{h}_{-i})$  remain meaningful as a reduced-form average labor demand elasticity, in which the wage of worker  $i$  is changed but with  $\mathbf{h}_{-i}$  held fixed. Furthermore, bunching is still informative about identifying the buncher ATE: bunching will not occur unless  $\Delta_i > 0$  from some units near the kink such that  $h_{0i} \in [k, k + \Delta_i]$ . The question is whether the treatment effects  $\Delta$  remain a good guide to the overall effect of the FLSA, given that it may also change  $\mathbf{h}_{-i}$  for a given worker  $i$ .

For concreteness, let us now suppose that hours are chosen to maximize profits with a joint-production function  $F(\mathbf{h})$ , where  $\mathbf{h}$  is a vector of the hours this week across all workers in the firm. We then have that  $(h_i, \mathbf{h}_{-i}) = \operatorname{argmax} \left\{ F(\mathbf{h}) - \sum_j B_{kj}(h_j) \right\}$ , where the sum is across workers  $j$  and  $B_{kj}(h) := w_j h + .5w_j \mathbb{1}(h > 40)(h - 40)$ . Similarly  $(h_i^*, \mathbf{h}_{-i}^*) = \operatorname{argmax} \left\{ F(\mathbf{h}) - \sum_j w_j h_j \right\}$ . Whether  $\mathbf{h}_{0i}(\mathbf{h}_{-i})$  is smaller or larger than  $h_i^*$  (with a fixed set of employees) will depend upon whether  $i$ 's hours are complements or substitutes in production with those of each of their colleagues, and with what strength. It is natural to expect that either case might occur. Consider for example a production function in which workers are divided into groups  $\theta_1 \dots \theta_M$  corresponding to different occupations, and:

$$F(\mathbf{h}) = \prod_{m=1}^M \left( \left( \sum_{i \in \theta_m} a_i \cdot h_i^{\rho_m} \right)^{1/\rho_m} \right)^{\alpha_m} \quad (3)$$

where  $a_i$  is an individual productivity parameter for worker  $i$ . The hours of workers within an occupation enter as a CES aggregate with substitution parameter  $\rho_m$ , which then combine in a Cobb-Douglas form across occupations with exponents  $\alpha_m$ . For this production function, the hours of two workers  $i$  and  $j$  belonging to different occupations are always complements in production: i.e.  $\partial_{h_i} F(\mathbf{h})$  is increasing in  $h_j$ . When  $i$  and  $j$  belong to the same occupation  $\theta_m$ , it can be shown that worker  $i$  and  $j$ 's hours are substitutes—i.e.  $\partial_{h_i} F(\mathbf{h})$  is *decreasing* in  $h_j$ —when  $\alpha_m \leq \rho_m$ .

Thus both substitution and complementarity in hours can plausibly coexist within a firm, and it is difficult to sign theoretically the overall contribution of interdependencies on our parameter of interest  $\theta$  (c.f. Eq. (9)). Given that neither occupations nor tasks are observed in the data, it is also difficult to obtain direct evidence even with the aid of functional-form assumptions like Eq. (3). I therefore turn to an indirect empirical test of whether these effects are likely to play a significant role in  $\theta$ .

An ideal test of interdependencies between hours within a firm would leverage random individual-level shocks to a worker's hours, and look for a response in the hours of their colleagues. A worker taking sick-pay—thus reducing their hours of work—represents a compelling candidate as its timing may be uncorrelated with that of firm-level shocks (after controlling for seasonality). Figure 10 uses an event study design to show that in weeks when a worker receives a positive number of sick-pay hours, their individual hours worked for that

week decline by about 8 hours on average. Yet I fail to find evidence of a corresponding change in the hours of others in the same firm. This suggests that short term variation in the hours of a worker’s colleagues does not tend to translate into contemporaneous changes in their own (for example, if the firm were dividing a fixed number of hours across workers). Figure 11 produces similar results when repacing the two-wage-fixed specification of Figure 10 with an “imputation”-based approach similar to Borusyak et al. (2021) and Gardner (2021).

Table 12 shows another piece of evidence: that my overall effect estimates are similar between small, medium, and large firms. If firms were to compensate for overtime hours reductions by “giving” some hours to similar workers who would otherwise be working less than 40, for instance, then we would expect this to play a larger role in firms where there are a large number of substitutable workers—causing a bias that increases with firm size.

	$p=0$		$p$ from PTO	
	Bunching	Effect of the kink	Net Bunching	Effect of the kink
Small firms	0.198 [0.189, 0.208]	[-1.525, -1.455] [-1.676, -1.299]	0.027 [0.023, 0.031]	[-0.231, -0.171] [-0.274, -0.139]
Medium firms	0.103 [0.095, 0.110]	[-1.123, -0.786] [-1.237, -0.710]	0.030 [0.025, 0.035]	[-0.337, -0.224] [-0.407, -0.178]
Large firms	0.050 [0.047, 0.054]	[-0.768, -0.468] [-0.861, -0.414]	0.024 [0.021, 0.028]	[-0.371, -0.224] [-0.444, -0.180]

**Table 12:** Estimates of the ex-post effect of the kink by firm size. “Small” firms have between 1 and 25 workers, “Medium” have 26 to 50, and “Large” have more than 50. Note that the estimated net bunching caused by the FLSA is similar across firm sizes (right), despite the raw bunching observed in the data differing by firm size category.

**Figure 10:** Event study coefficients  $\beta_j$  and 95% confidence intervals across an instance of a worker receiving pay for non-work hours (either sick pay, holiday pay, or paid time off-‘PTO’). Confidence intervals are constructed by non-parametric bootstrap clustered by firm. Estimating equation is  $y_{it} = \mu_t + \lambda_i + \sum_{j=-3}^{10} \beta_j D_{it,j} + u_{it}$ , where  $D_{it,j} = 1$  if worker  $i$  in week  $t$  has a positive number of a given type of non-work hours  $j$  weeks ago (after a period of at least three weeks in which they did not),  $\lambda_i$  are worker fixed effects, and  $\mu_t$  are calendar week effects. Rows correspond to choices of the non-work pay type: either sick, holiday, PTO. Columns indicate choices of the outcome  $y_{it}$ . “Colleague hours worked” sums the hours of work in  $t$  across all workers other than  $i$  in  $i$ ’s firm. The timing of both holiday and PTO hours appears to be correlated across workers, leading to a decrease in the working hours of  $i$ ’s colleagues in weeks in which  $i$  takes either holiday or PTO pay (center-right and bottom-right graphs). However I cannot reject that colleague work hours are unrelated to an instance of sick pay: before, during and after it occurs (top-right). Meanwhile  $i$ ’s hours of work reduce by about 8 hours on average during an instance of sick pay (top-center). This suggests that there is no contemporaneous reallocation of  $i$ ’s forgone work hours to their colleagues.

**Figure 11:** This figure replaces the two-way-fixed-effects estimator used in Figure 10 with an “imputation” approach similar to Borusyak et al. (2021) and Gardner (2021). Results are very similar to those in Figure 10. Specifically, I call all observations that are not between 3 weeks before and 10 weeks after a spell of non-work hours “clean controls”, and estimate a first regression  $y_{it} = \mu_t + \lambda_i + \epsilon_{it}$  using these observations only. This regression includes all paychecks for workers that never have the corresponding type of non-work hour (sick pay, holiday pay, or PTO), but also a subset of paychecks for nearly all workers who do have a spell of non-work hours at some point (allowing me to estimate their fixed effect  $\lambda_i$ ). Given the  $\hat{\mu}_t$  and  $\hat{\lambda}_i$ , I compute  $\tilde{y}_{it} = y_{it} - \hat{\mu}_t - \hat{\lambda}_i$  among units that are not clean controls (i.e. those between  $-3$  and  $10$  weeks after the start of a spell), and estimate a second regression  $\tilde{y}_{it} = \sum_{j=-3}^{10} \beta_j D_{it,j} + e_{it}$  on these units only (dropping a small number of workers  $i$  for whom there were no clean-control observations). 95% confidence intervals are constructed by non-parametric bootstrap clustered by firm.

## H Modeling the determination of wages and “typical” hours

### H.1 A simple model with exogenous labor supply

Each firm faces a labor supply curve  $N(z, h)$ , indicating the labor force  $N$  it can maintain if it offers total compensation  $z$  to each of its workers, when they are each expected to work  $h$  hours per week. The firm chooses a pair  $(z^*, h^*)$  based on the cost-minimization problem:

$$\min_{z, h, K, N} N \cdot (z + \psi) + rK \text{ s.t. } F(Ne(h), K) \geq Q \text{ and } N \leq N(z, h) \quad (4)$$

where the labor supply function is increasing in  $z$  while decreasing in  $h$ ,  $e(h)$  represents the “effective labor” from a single worker working  $h$  hours, and  $\psi$  represents non-wage costs per worker. The quantity  $\psi$  can include for example recruitment effort and training costs, administrative overhead and benefits that do not depend on  $h$ . Concavity of  $e(h)$  captures declining productivity at longer hours, for example from fatigue or morale effects. The function  $F$  maps total effective labor  $Ne(h)$  and capital into level of output or revenue that is required to meet a target  $Q$ , and  $r$  is the cost of capital  $K$ . For simplicity, workers within a firm are here identical and all covered by the FLSA.

To understand the properties of the solution to Equation (4), let us examine two illustrative special cases.

### Special case 1: an exogenous competitive straight-time wage (the “fixed-wage model”)

Much of the literature on hours determination has taken the hourly wage as a fixed input to the choice of hours, and assumed that at that wage the firm can hire any number of workers, regardless of hours. This can be motivated as a special case of Equation (4) in which there is perfect competition on the straight-time wage, i.e.  $N(z, h) = \bar{N}\mathbb{1}(w_s(z, h) \geq w)$  for some large number  $\bar{N}$  and wage  $w$  exogenous to the firm, where the function  $w_s(\cdot)$  is defined in Equation (1). Then Equation (4) reduces to:

$$\min_{N, h, K} N \cdot (hw + \mathbb{1}(h > 40)(w/2)(h - 40) + \psi) + rK \text{ s.t. } F(Ne(h), K) \geq Q \quad (5)$$

By limiting the scope of labor supply effects in the firm’s decision, Equation (5) is well-suited to illustrating the competing forces that shape hours choice on the production side: namely the fixed costs  $\psi$  on the one hand and the concavity of  $e(h)$  on the other. Were  $\psi$  equal to zero with  $e(h)$  strictly concave globally, a firm solving Equation (5) would always find it cheaper to produce a given level of output with more workers working less hours each. On the other hand, were  $\psi$  positive and  $e$  weakly convex, it would always be cheapest to hire a single worker to work all of the firm’s hours. In general, fixed costs and declining hours productivity introduce a tradeoff that leads to an interior solution for hours.<sup>5</sup>

Equation (5) introduces a kink into the firm’s costs as a function of hours, much as short-run wage rigidity does in my dynamic analysis. However, the assumption that the firm can demand any number of hours at a set straight-time wage rate is harder to defend when thinking about firms long-run expectations, a point emphasized by Lewis (1969). Equilibrium considerations will also tend to run against the independence of hourly wages and hours - a mechanism explored in Appendix H.2.

---

<sup>5</sup>In the fixed-wage special case, these two forces along with the wage are in fact sufficient to pin down hours, which do not depend on the production function  $F$  or the chosen output level  $Q$ . See e.g. Cahuc and Zylberberg (2014) for the case in which  $e(h)$  is iso-elastic.

## Special case 2: iso-elastic functional forms (the “fixed-job model”)

By placing some functional form restrictions on Equation (4), we can obtain a closed-form expression for  $(z^*, h^*)$ . In particular, when both labor supply and  $e(h)$  are iso-elastic, production is separable between capital and labor and linear in the latter, and firms set the output target  $Q$  to maximize profits, Proposition H.1 characterizes the firm’s choice of earnings and hours:

**Proposition H.1.** *When i)  $e(h) = e_0 h^\eta$  and  $N(z, h) = N_0 z^{\beta_z} h^{\beta_h}$ ; ii)  $F(L, K) = L + \phi(K)$  for some function  $\phi$ ; and iii)  $Q$  is chosen to maximize profits, the  $(z^*, h^*)$  that solve Equation (4) are:*

$$h^* = \left[ \frac{\psi}{e_0} \cdot \frac{\beta}{\beta - \eta} \right]^{1/\eta} \quad \text{and} \quad z^* = \psi \cdot \frac{\beta_z}{\beta_z + 1} \frac{\eta}{\beta - \eta}$$

where  $\beta := \frac{|\beta_h|}{\beta_z + 1}$ , provided that  $\psi > 0$ ,  $\eta \in (0, \beta)$ ,  $\beta_h < 0$  and  $\beta_z > 0$ . Hours and compensation are both decreasing in  $|\beta_h|$  and increasing in  $\beta_z$ .

*Proof.* See Appendix D. □

The proposition shows that the hours chosen depend on labor supply via  $\beta = \frac{|\beta_h|}{1 + \beta_z}$ , which gauges how elastic labor supply is with respect to hours relative to earnings. The more sensitive labor supply is to a marginal increase in hours as compared with compensation, the higher  $\beta$  will be and lower the optimal number of hours. The proof of Proposition H.1 also shows that the general model with  $N(z, h)$  differentiable (unlike in Special Case 1) can support an interior solution for hours even without fixed costs  $\psi = 0$ . Proposition H.1 provides an example of the *fixed-job* model: in the absence of perfect competition on the straight-wage, anticipated hours  $h^*$ , total pay  $z^*$ , and employment  $N^* := N_0 \cdot (z^*)^{\beta_z} (h^*)^{\beta_h}$  are unaffected by the FLSA overtime rule, in this simple static model.

## H.2 Endogenizing labor supply in an equilibrium search model

The last section treated the labor supply function  $N(z, h)$  as exogenous, but in general it might be viewed as an equilibrium object that reflects both worker preferences over income/leisure and the competitive environment for labor. It is conceivable that equilibrium forces would lead to a labor supply function like that of the fixed-wage model, in which the FLSA has an effect on the hours set at hiring.

In this section, I show that the prediction of the fixed-job model that the FLSA has little to no effect on  $h^*$  or  $z^*$  is robust to embedding Equation (4) into an extension of the Burdett and Mortensen (1998) model of equilibrium with on-the-job search.<sup>6</sup> In the context of the search model, the only effect of the overtime rule on the distribution of  $h^*$  is mediated

---

<sup>6</sup>This remains true even in the perfectly competitive limit of the model, the basic reason being that workers choose to accept jobs on the basis of their known total earnings  $z^*$ , rather than the straight-time wage.

through the minimum wage, which rules out some of the  $(z^*, h^*)$  pairs that would occur in the unregulated equilibrium. In a numerical calibration, this effect is quite small, suggesting that equilibrium effects play only a minor role in how the FLSA overtime rule impacts anticipated hours or straight-time wages. This motivates the strategy in Section 4.4, in which  $z^*$  and  $h^*$  are treated as fixed when considering the impact of the FLSA on straight-wages.

### H.2.1 The model

I focus on a minimal extension of Burdett and Mortensen (1998) that takes firms to be homogeneous in their technology and workers to be homogeneous in their tastes over the tradeoff between income and working hours.<sup>7</sup> Let there be a large number  $N_w$  of workers and large number  $N_f$  of firms, and define  $m = N_w/N_f$ .<sup>8</sup> Formally, we model this as a continuum of workers with mass  $m$ , and continuum of firms with unit mass. Firms choose a value of pay  $z$  and hours  $h$  to apply to all of their workers. Each period, there is an exogenous probability  $\lambda$  that any given worker receives a job offer, drawn uniformly from the set of all firms. Employed workers accept a job offer when they receive an earnings-hours package that they prefer to the one they currently hold, where preferences are captured by a utility function  $u(z, h)$  taken to be homogeneous across workers and strictly quasiconcave, where  $u_z > 0$  and  $u_h < 0$ . If a worker is not currently employed, they leave unemployment for a job offer if  $u(z, h) \geq u(b, 0)$ , where  $b$  represents a reservation earnings level required to incent a worker to enter employment. Workers leave the labor market with probability  $\delta$  each period, and an equal number enters the non-employed labor force.

Before we turn to earnings-hours posting decision of firms, we can already derive several relationships that must hold for the earnings-hours distribution in a steady state equilibrium. First note that the share unemployed  $v$  of the workforce must be  $v = \frac{\delta}{\delta + \lambda}$ , since mass  $m(1-v)\delta$  enters unemployment each period, and  $m\lambda v$  leaves (taking for granted here that firms only post job offers that are preferred to unemployment, which is indeed a feature of the actual equilibrium). Let's say that job  $(z, h)$  is "inferior" to  $(z', h')$  when  $u(z, h) \leq u(z', h')$ . Let  $P_{ZH}$  be the firm-level distribution over offers  $(Z_j, H_j)$ , and define

$$F(z, h) := P_{ZH}(u(Z_j, H_j) \leq u(z, h)) \quad (6)$$

to be the fraction of firms offering inferior job packages to  $(z, h)$ . The separation rate of workers at a firm choosing  $(z, h)$  is thus:  $s(z, h) = \delta + \lambda(1 - F(z, h))$ . To derive the recruitment

---

<sup>7</sup>The model presented here bears similarity to that of Hwang et al. (1998), which also considers search equilibrium with non-wage amenities such as hours. My model generalizes the preferences of workers to be possibly non-quasilinear, which allows my model to support hours dispersion in equilibrium, even with identical firms. In their model, by contrast, firms are allowed to be heterogeneous but all firms with the same production technology would offer the same quantity of hours.

<sup>8</sup>Here we largely follow the notation of the presentation of the Burdett & Mortensen model by Manning (2003).

of new workers to a given firm each period, we define the related quantity  $G(z, h)$  – the fraction of employed workers that are at inferior firms to  $(z, h)$ . In a steady state, note that  $G(z, h)$  must satisfy

$$\underbrace{m(1 - v) \cdot G(z, h)(\delta + \lambda(1 - F(z, h)))}_{\text{mass of workers leaving set of inferior firms}} = \underbrace{mv\lambda F(z, h)}_{\text{mass of workers entering set of inferior firms}}$$

since the number of workers at firms inferior to  $(z, h)$  is assumed to stay constant. To get the RHS of the above, note that workers only enter the set of firms inferior to  $(z, h)$  from unemployment, and not from firms that they prefer. This expression allows us to obtain the recruitment function  $R(z, h)$  to a firm offering  $(z, h)$ . Recruits will come from inferior firms and from unemployment, so that

$$R(z, h) = \lambda m ((1 - v)G(z, h) + v) = m \left( \frac{\delta \lambda}{\delta + \lambda(1 - F(z, h))} \right)$$

Combining with the separation rate, we obtain the steady-state labor supply function facing each firm:

$$N(z, h) = R(z, h)/s(z, h) = \frac{m\delta\lambda}{(\delta + \lambda(1 - F(z, h)))^2} \quad (7)$$

Eq. (7) is analogous to the baseline Burdett and Mortensen model without hours, with the quantity  $F(z, h)$  playing the role of the firm-level CDF of wages from the baseline model.

Now we turn to how the form of  $F(z, h)$  in general equilibrium. We take the profits of firms to be

$$\pi(z, h) = N(z, h)(p(h) - z) = m\delta\lambda \cdot \frac{p(h) - z}{(\delta + \lambda(1 - F(z, h)))^2} \quad (8)$$

where the function  $p(h)$  corresponds to net revenue per worker  $e(h) - \psi$ , with  $e(h)$  being some weakly concave and increasing function with  $e(0) = 0$ , and  $\psi$  recurring non-wage costs per worker. To simplify some of the exposition, we will emphasize the simplest case of  $p(h) = p \cdot h$ , such that worker hours are perfectly substitutable across workers.

In equilibrium, the identical firms each playing a best response to  $F(z, h)$ , and thus all choices of  $(z, h)$  in the support of  $P_{ZH}$  must yield the same level of profits  $\pi^*$ . This gives an expression for  $F(z, h)$  over all  $(z, h)$  in the support of  $P_{ZH}$ , in terms of  $\pi^*$ :

$$F(z, h) = 1 + \frac{\delta}{\lambda} - \sqrt{\frac{m\delta}{\lambda} \cdot \frac{p(h) - z}{\pi^*}} \quad (9)$$

It follows from Eqs. (9) and (7) that we can rank firms in equilibrium by  $F(z, h)$  and therefore by size according to the quantity  $z - p(h)$ . Since Eq. (7) is continuously differentiable

in  $(z, h)$ , we can rule out mass points in  $P_{ZH}$  by an argument paralleling that in Burdett and Mortensen (1998).<sup>9</sup>

To fully characterize the equilibrium, first note that  $P_{ZH}$  can put a positive density on at most one point along each isoquant of  $z - p(h)$ , given that utility is strictly quasiconcave but  $z - p(h)$  is weakly convex. Offers in the support of  $P_{ZH}$  thus lie along a one dimensional path through  $\mathbb{R}^2$ , and we can parametrize them by a scalar  $t \in [0, 1]$ , such that  $\text{supp}(P_{ZH}) = \{(z(t), h(t))\}_{t \in [0, 1]}$  and  $t = F(z(t), h(t))$ . Observe that each  $(z(t), h(t))$  must pick out the point along its respective isoquant of  $z - p(h)$  which delivers the highest utility to workers, i.e.:

$$(z(t), h(t)) = \text{argmax}_{z, h} u(z, h) \text{ s.t. } z - p(h) = \eta(t) \quad (10)$$

where  $\eta(t) = \frac{\pi^* \lambda}{m \delta} (1 - \frac{t}{1 + \delta/\lambda})^2$  is the value of  $p(h(t)) - z(t)$  such that  $F(z(t), h(t)) = t$  according to Eq.(9), viewed as a function of  $t$ .<sup>10</sup> The slope of the path  $(z(t), h(t))$  can be derived from the first order condition for the above problem and the implicit function theorem:

$$\frac{z'(t)}{h'(t)} = - \frac{u_{hh}(z, h) + p''(h)u_z(z, h) + p'(h)u_{zh}(z, h)}{p'(h)u_{zz}(z, h) + u_{zh}(z, h)} \Big|_{(z, h) = (z(t), h(t))}$$

If preferences were quasilinear in income, then the curve  $AB$  shown in Figure 12 would be a vertical line rising from point  $A$  and there would be no hours dispersion in equilibrium (as in Hwang et al., 1998). Figure 12 instead depicts the path  $\{(z(t), h(t))\}_{t \in [0, 1]}$  for a generic case in which preferences are neither homothetic nor quasilinear. If preferences were homothetic  $AB$  would be a straight line.

To pin down the initial point  $A$ , we note that it must lie on the indifference curve passing through the unemployment point  $(b, 0)$ , labeled as  $IC_b$  in Figure 12.<sup>11</sup> I assume that the marginal rate of substitution between compensation and hours is less than  $p'(0)$  at  $(z, h) = (b, 0)$  (such that there are gains from trade) and increases continuously with  $h$ , eventually passing  $p'(h)$  at some point  $h^*$ . This point is unique given strict quasiconcavity of  $u(\cdot)$ .

Let  $z^*$  be the earnings value such that workers are indifferent between  $(z^*, h^*)$  and unemployment  $(b, 0)$ , which represents a reservation level of utility required to enter employment.

---

<sup>9</sup>Suppose  $P_{ZH}(z, h) = \delta > 0$  for some  $(z, h)$ . Then any firm located at  $(z, h)$  and earning positive profits could increase their profits further by offering a sufficiently small increase in compensation (or reduction in hours, or a combination of both). Since  $F(z + \delta_z, h) = F(z, h) + \delta$  to first order, there exists a small enough  $\delta_z$  such that  $\pi(z + \delta_z, h) > \pi(z, h)$  by Eq. (8).

<sup>10</sup>If instead we had  $u(z(t), h(t)) < \max_{(z, h): z - p(h) = F^{-1}(t)} u(z, h)$ , then any firm located at  $(z(t), h(t))$  could profitably deviate to the argmax while keeping profits per worker constant but increasing their labor supply by attracting workers from  $(z(t), h(t))$ .

<sup>11</sup>If it were to the northwest of the  $IC_b$  curve, a firm located there could increase profits by offering a lower value of  $z - p(h)$ , since given that  $F(z(0), h(0)) = 0$  their steady state labor supply already only recruits from unemployment. However, they cannot offer a pair that lies to the southeast of  $IC_b$ , since they could never attract workers from unemployment.

**Figure 12:** The support of the equilibrium distribution of compensation-hours offers  $(z, h)$  lies along the arrowed (blue) curve  $AB$ . Figure shows the case of perfect hours substitutability  $p(h) = ph$ . Plain curve  $IC_b$  is the indifference curve passing through the unemployment point  $(b, 0)$ . The least desirable firm in the economy lies at the pair  $(z^*, h^*)$ , labeled by  $A$ , where  $IC_b$  has a slope of  $p$ . The other points chosen by firms are found by starting at point  $A$  and moving in the direction of higher utility, while maintaining a marginal rate of substitution of  $p$  between hours and earnings. This path intersects the line of solutions to  $F(z, h) = 1$  given Eq. (9) at point  $B$ . Note that this line still lies below the zero profit line  $z = ph$ , as firms make positive profit.

Using that  $F(z^*, h^*) = 0$  and  $\pi^* = \pi(z^*, h^*)$ , we can rewrite Equation (9) as:

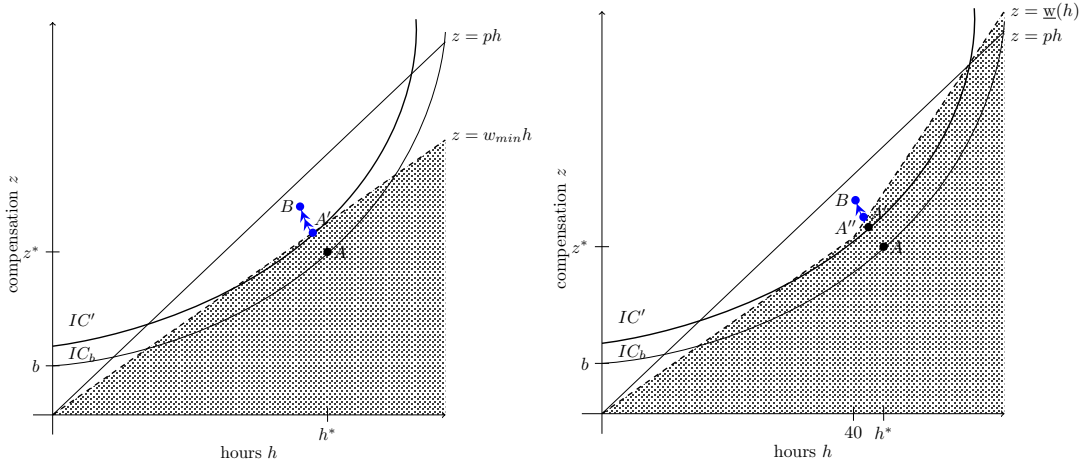

$$F(z, h) = \left(1 + \frac{\delta}{\lambda}\right) \left[1 - \sqrt{\frac{p(h) - z}{p(h^*) - z^*}}\right] \quad (11)$$

The firms at point  $B$  in Figure 12 thus solve  $z - p(h) = \left(\frac{\delta}{\delta + \lambda}\right)^2 (z^* - p(h^*))$ , and equilibrium profits are  $\pi^* = m(p(h^*) - z^*) \cdot \frac{\lambda/\delta}{(1 + \lambda/\delta)^2}$ . Note that in equilibrium, there exists dispersion not only in both earnings and in hours (provided preferences are not quasi-linear), but also in effective hourly wages, as the ratio  $z(t)/h(t)$  is also strictly increasing with  $t$ . Note that  $\pi^*$  goes to zero in the limit that  $\lambda/\delta \rightarrow \infty$ . In this limit dispersion over hours, earnings, and hourly earnings all disappear as the line  $AB$  collapses to a single point on the zero profit line  $z = p(h)$ .<sup>12</sup>

<sup>12</sup>Note that there is no contradiction here as the argument that point  $A$  must be on  $IC_b$  relies on  $F(z(0), h(0)) = 0$ , which is implied by no mass points in  $P_{ZH}$ , in turn implied by firms making positive profit.

### H.2.2 Effects of FLSA policies

Now consider the introduction of a minimum wage, which introduces a floor on the hourly wage  $w := z/h$ . I assume that the point  $(z^*, h^*)$  does not satisfy the minimum wage, so that the minimum wage binds and rules out part of the unregulated support of  $P_{ZH}$ . The left panel of Figure 13 depicts the resulting equilibrium, in which the initial point  $(z(0), h(0))$  moves to the point marked  $A'$ , at which the marginal rate of substitution between compensation and hours is  $p'(h)$ , but the compensation-hours pair just meets the minimum wage. This compresses the distribution  $P_{ZH}$  compared with the unregulated equilibrium from Figure 12, which now follows a subset of the original path  $AB$ , reflecting a reduction in hours and an increase in total compensation.

**Figure 13:** Left panel shows the support of the equilibrium distribution of compensation-hours offers  $(z, h)$  under a binding minimum wage. The compensation hours pairs that do not meet  $\underline{w}$  are indicated by the shaded region. The lowest-wage offer in the economy moves from point  $A$  in the unregulated equilibrium to the point  $A'$  on the minimum wage line  $z = \underline{w}h$  at which the marginal rate of substitution between compensation and hours equals  $p$ . Right panel shows how this effect is augmented when overtime premium pay for hours in excess of 40 is required, and  $A'$  lies at greater than 40 hours. In this case the support of  $P_{ZH}$  begins at point  $A''$ , which lies on the kinked minimum wage function  $\underline{w}(h)$ .

The right panel of Figure 13 shows how equilibrium is further affected if in addition to a binding minimum wage, premium pay is required at a higher minimum wage  $1.5\underline{w}$  for hours in excess of 40, provided that the point  $A'$  lies at an hours value that is greater than 40. In this case,  $(z(0), h(0))$  will lie at point  $A''$ , at which the marginal rate of substitution between compensation and hours is equal to  $h'$ , and compensation is equal to the minimum-compensation function under both the minimum wage and overtime policies.

### H.2.3 Calibration

To allow wealth effects in worker utility while facilitating calibration based on existing empirical studies, I take worker utility to follow the Stone-Geary functional form:

$$u(z, h) = \beta \log(z - \gamma_z) + (1 - \beta) \log(\gamma_h - h)$$

This simple specification allows a closed form solution to the path  $(z(t), h(t))$ , given by the following Proposition, which follows from the optimization problem (10) and working out the initial point  $(z(0), h(0))$  in each policy regime.

**Proposition.** *Under Stone-Geary preferences and linear production  $p(h) = ph - \psi$ , the equilibrium offer distribution is a uniform distribution over  $\{(z(t), h(t))\}_{t \in [0,1]}$ , where:*

$$\begin{pmatrix} z(t) \\ h(t) \end{pmatrix} = \begin{pmatrix} p\beta\gamma_h + (1 - \beta)\gamma_z - \beta\psi - \beta\eta(t) \\ \beta\gamma_h + \frac{1-\beta}{p}(\gamma_z + \psi) + \frac{(1-\beta)}{p}\eta(t) \end{pmatrix}$$

where  $\eta(t) = \left(1 - \frac{t}{1+\delta/\lambda}\right)^2 \cdot (ph(0) - z(0) - \psi)$ . The initial point  $(z(0), h(0))$  is

1.  $h(0) = \gamma_h - \left(\frac{(b-\gamma_c)(1-\beta)}{p\beta}\right)^\beta \gamma_h^{1-\beta}$  and  $z(0) = z^* = \gamma_z + \left(\frac{p\beta\gamma_h}{1-\beta}\right)^{1-\beta} ((b - \gamma_c)(1 - \beta))^\beta$  in the unregulated equilibrium
2.  $h(0) = (\frac{p\beta}{1-\beta}\gamma_h + \gamma_z)(\underline{w} - \frac{p\beta}{1-\beta})^{-1}$  and  $z(0) = \underline{w}h(0)$  with a binding minimum wage of  $\underline{w}$  (binding in the sense that  $z^* < \underline{w}h^*$ )
3.  $h(0) = (\frac{p\beta}{1-\beta}\gamma_h + \gamma_z + 20\underline{w})(1.5\underline{w} - \frac{p\beta}{1-\beta})^{-1}$  and  $z(0) = 1.5\underline{w}h(0) - 20\underline{w}$  with a minimum wage of  $\underline{w}$  and time-and-a-half overtime pay after 40 hours, if the expression for  $h(0)$  in item 2. is greater than 40

Moments with respect to the worker distribution can be evaluated for any measurable function  $\phi(z, h)$  as:

$$E_{workers}[\phi(Z_i, H_i)] = \left(1 + \frac{\lambda}{\delta}\right) \int_0^1 \phi(z(t), h(t)) \cdot \left(1 + \frac{\lambda}{\delta}(1 - t)\right)^{-2} dt$$

I calibrate the model focusing on a lower-wage labor market where productivity is a constant  $p = \$15$ . I allow non-wage costs of  $\psi = \$100$  a week, with the value based on estimates of benefit costs in the low-wage labor market.<sup>13</sup> I take  $b = \$250$  corresponding to unemployment benefits that can be accrued at zero weekly hours of work.<sup>14</sup> I calibrate

<sup>13</sup>Specifically, I take a benefit cost of \$2.43 per hour worked for the 10th percentile of wages in 2019: BLS ECEC, multiplied by the average weekly hours worked of 42.5 from the 2018 CPS summary, which results in  $102.425 \approx 100$ .

<sup>14</sup>I use the UI replacement rate for single adults 2 months after unemployment from the OECD. Taking this for individuals at 2/3 of average income (the lowest available in this table), and then use a BLS figure for average income at the 10% percentile of 22,880, we have  $b \approx \$22,880 \cdot 0.6/52.25 = \$263$

the factor  $\lambda/\delta$  using estimates from Manning (2003) using the proportion of recruits from unemployment. Using Manning’s estimates from the US in 1990 of about 55% of recruits coming from unemployment, this implies a value of  $\lambda/\delta \approx 3$  in the baseline Burdett and Mortensen (1998) model.

To calibrate the preference parameters, I first pin down  $\beta$  from estimates of the marginal propensity to reduce earnings after random lottery wins (Imbens et al. 2001; Cesarini et al. 2017). Both of these studies report a value in the neighborhood of  $\beta = 0.85$ . I take a value of  $\gamma_z = \$200$  as the level of consumption at which the marginal willingness to work is infinite, and take  $\gamma_h = 50$  hours of work per week. I choose this value according to a rule-of-thumb as the average hours among full-time workers in the US (42.5), divided by  $\beta$ .<sup>15</sup>

Given these values, we can compute moments of functions of the joint distribution of compensation and hours using the Proposition and numerical evaluation of the integrals. Table 13 reports worker-level means of hours, weekly compensation, and the hourly wage  $z/h$ , as well as employment and profits per worker averaged across the firm distribution. In the unregulated equilibrium, the lowest-compensated workers work about 49 hours a week earning about \$300, while the highest-compensated workers work about 46 hours and earn more than \$550. This equates to a more than doubling of the hourly wage, which is about \$6 for the  $t = 0$  workers and over \$12 for the  $t = 1$  workers. For each of the first three variables, the mean across workers is much closer to the  $t = 1$  value than the  $t = 0$  value (the largest firm is about 16 times as large as the smallest).

	<i>Unregulated equilibrium</i>			$\underline{w} = 7.25$	$\underline{w} = 7.25$ & OT	$\underline{w} = 12$ & OT
	t=0	t=1	mean	mean	mean	mean
weekly hours	48.85	45.71	46.34	46.18	46.11	45.51
weekly earnings	297.36	564.68	511.22	524.31	530.93	581.78
hourly wage	6.09	12.35	11.06	11.37	11.53	12.78
firm size / smallest	1.00	16.00	4.00	4.00	4.00	4.00
weekly profit per worker	335.46	20.97	146.76	119.81	106.18	1.49

**Table 13:** Results from the calibration. The parameter  $t \in [0, 1]$  indicates firm rank in desirability from the perspective of workers. Means for weekly hours, weekly earnings, and hourly wages are computed with respect to the worker distribution, while firm size and profits per worker is averaged with respect to the firm distribution.

The third column of Table 13 adds a minimum wage set at the current federal rate of \$7.25. This provides a small increase of about 30 cents to the average hourly wage, which now begins at \$7.25 for  $t = 0$  rather than \$6.06. Note that the minimum wage provides spillovers by reallocating firm mass up the entire wage ladder, beyond the mechanical effect

<sup>15</sup>Cesarini et al. (2017) point out that when  $\gamma_c$  and no-earned income, optimal hours choice is  $\beta\gamma_h$ . By comparison, these authors calibrate  $\gamma_h$  to be about 35 hours in the Swedish labor market.

of increasing the wages of those previously below 7.25. Average hours worked are decreased slightly due to the minimum wage, by about ten minutes per week. As this effect is mediated by a wealth effect in labor supply, we can expect it to be small unless worker preferences deviate significantly from quasi-linearity with respect to income. With  $\beta = .85$ , this effect is reasonably modest but non-negligible. In the fourth column, we see that the combination of the minimum wage and overtime premium has little effect beyond the direct effect of the minimum wage: hourly earnings increase another 15 cents and hours worked go down by another 0.07. Finally, we see that increasing the minimum wage to \$12 has much larger effects: adding another dollar to average wages and reducing working time by a bit more than half an hour per week. Given the fixed costs assumed in this calibration, a \$12 minimum wage causes employers to run on extremely thin margins for these workers (who have \$15 an hour productivity). However, note that in this model a minimum wage causes neither an increase nor decrease in aggregate non-employment, as this is governed in the steady state only by  $\lambda/\delta$ . Thus, the average absolute firm size is unchanged across the policy environments.

## I Further identification results for the bunching design

This section presents several additional sufficient conditions for point or partial identification in the bunching design, beyond Theorem 1 from the main text. In this section, I continue with the notation  $Y_i$  rather than  $h_{it}$  as in Appendix B. For simplicity, I in this section assume that  $Y_0$  and  $Y_1$  admit a density everywhere so there is no counterfactual bunching at the kink. However, the results here can be applied given a known  $p = P(Y_{0i} = Y_{1i} = k)$ , as in Section 4.3, by trimming  $p$  from the observed bunching and re-normalizing the distribution  $F(y)$ .

I first consider parametric assumptions when treatment effects are assumed homogeneous, recasting some existing results from the literature into my generalized framework. Then I turn to nonparametric restrictions that also assume homogeneous treatment effects, before stating some results with heterogeneous treatments.

### I.1 A generalized notion of homogeneous treatment effects

Recall that in the isoelastic model, treatment effects are homogeneous across units after a log transformation of the choice variable  $y$ . In order to formalize and generalize results from the literature that have focused on the isoelastic model, let begin with a generalized notion of homogenous treatment effects. For any strictly increasing and differentiable transformation  $G(\cdot)$ , let us define for each unit  $i$ :

$$\delta_i^G := G(Y_{0i}) - G(Y_{1i})$$

The iso-elastic model common in the bunching-design literature predicts that while  $\Delta_i$  is heterogeneous across  $i$ ,  $\delta_i^G$  is homogeneous when  $G$  is taken to be the natural logarithm func-

tion. In this case  $\Delta_i^G$  is proportional to a reduced form elasticity measuring the percentage change in  $y_i(\mathbf{x})$  when moving from constraint  $B_{1i}$  to  $B_{0i}$ . In particular, in the simplest case of a bunching design in which  $B_0$  and  $B_1$  are linear functions of  $y$  with slopes  $\rho_0$  and  $\rho_1$  respectively, and utility follows the iso-elastic quasi-linear form of Equation (3), we have:

$$\delta_i^G = \delta := |\epsilon| \cdot \ln(\rho_1/\rho_0)$$

for all units  $i$ , when  $G$  is taken to be the natural logarithm.

Note that under CHOICE and CONVEX the result of Lemma B.1 holds with  $G(\cdot)$  applied to each of  $Y_i$ ,  $Y_{0i}$ , and  $Y_{1i}$ , since  $G$  is strictly increasing. When  $\delta_i^G$  is homogeneous for some  $G$  with common value  $\delta$ , we thus have that  $\mathcal{B} = P(G(Y_{0i}) \in [G(k), G(k) + \delta])$  by Proposition B.1. Since  $G(\cdot)$  is strictly increasing, we can still write the bunching condition in terms of counterfactual “levels”  $Y_{0i}$  as

$$\mathcal{B} = P(Y_{0i} \in [k, k + \Delta]) \text{ where } \Delta = G^{-1}(G(k) + \delta) - k \quad (12)$$

For example,  $\Delta = k(e^\delta - 1)$  in the iso-elastic model. The parameter  $\Delta$  is equal to the parameter  $\Delta_0^*$  introduced in Section 4.3, since  $\delta_i^G = \delta$  implies rank invariance between  $Y_{0i}$  and  $Y_{1i}$ .  $\Delta$  can be seen as a pseudo-parameter plays the same role as  $\Delta$  would in a setup in which we assumed a constant treatment effects in levels  $\Delta_i = \Delta$ . If it can be pinned down, it will also be possible to identify  $\delta$ . Nevertheless, it will be important to keep track of the function  $G$  when  $\delta_i^G$  is assumed homogeneous. For instance, homogeneous  $\delta_i^G = \delta$  implies that  $f_0^G(G(k) + \delta) = f_1^G(G(k))$  but not that  $f_0(k + \Delta) = f_1(k)$ , where  $f_d^G$  is the density of  $G(d_i)$  for each  $d \in \{0, 1\}$ .

## I.2 Parametric approaches with homogeneous treatment effects

The approach introduced by Saez 2010 assumes that the density  $f_0(y)$  is linear on the bunching interval  $[k, k + \Delta]$ . This affords point-identification of  $\epsilon$  in an iso-elastic utility model. We can use the notation above to provide the following generalization of this result:

**Proposition I.1 (identification by linear interpolation, à la Saez 2010).** *If  $\delta_i^G = \delta$  for some  $G$ ,  $F_1(y)$  and  $F_0(y)$  are continuously differentiable, and  $f_0(y)$  is linear on the interval  $[k, k + \Delta]$ , then with CONVEX, CHOICE:*

$$\mathcal{B} = \frac{1}{2} (G^{-1}(G(k) + \delta) - k) \left\{ \lim_{y \uparrow k} f(y) + \frac{G'(G^{-1}(G(k) + \delta))}{G'(k)} \lim_{y \downarrow k} f(y) \right\}$$

*Proof.* See Section D. □

In particular, given the iso-elastic model with budget slopes  $\rho_0$  and  $\rho_1$ :

$$\mathcal{B} = \frac{\Delta}{2} \left\{ \lim_{y \uparrow k} f(y) + \frac{k}{k + \Delta} \lim_{y \downarrow k} f(y) \right\} = \frac{k}{2} \left( \left( \frac{\rho_0}{\rho_1} \right)^\epsilon - 1 \right) \left( \lim_{y \uparrow k} f(y) + \left( \frac{\rho_0}{\rho_1} \right)^{-\epsilon} \lim_{y \downarrow k} f(y) \right) \quad (13)$$

which serves as the main estimating equation from Saez (2010) (and can be solved for  $\epsilon$  by the quadratic formula). The empirical approach of Saez (2010) can thus be seen as applying a result justified in a much more general model than the iso-elastic utility function assumed therein, provided that the researcher is willing to assume homogeneous treatment effects (possibly after some known transformation  $G$ , and/or conditional on observables).<sup>16</sup> Note that the linearity assumption of Proposition I.1 could be falsified by visual inspection: it implies that right and left limits of the derivative of the density of  $Y_i$  at the kink are equal.

A more popular approach, following Chetty et al. (2011), is to use a global polynomial approximation to  $f_0(y)$ , which interpolates  $f_0(y)$  inwards from both directions across the missing region of unknown width  $\Delta$ . This technique has the added advantage of accommodating diffuse bunching, for which the relevant  $\mathcal{B}$  is the total “excess-mass” around  $k$  rather than a perfect point mass at  $k$ . I focus here on the simplest case in which bunching is exact, as in the overtime setting. The polynomial approach can be seen as a special case of the following result:

**Proposition I.2 (identification from global parametric fit, à la Chetty et al. 2011).**

*Suppose  $f_0(y)$  exists and belongs to a parametric family  $g(y; \theta)$ , where  $f_0(y) = g(y; \theta_0)$  for some  $\theta_0 \in \Theta$ , and that  $\delta_i^G = \delta$  for some  $G$  and CONVEX and CHOICE hold. Then, if:*

1.  *$g(y; \theta)$  is an analytic function of  $y$  for all  $\theta \in \Theta$ , and*
2.  *$g(y; \theta_0) > 0$  for all  $y \in [k, k + \Delta]$ ,*

*it follows that  $\Delta$  (and hence  $\delta$ ) is identified as  $\Delta(\theta_0)$ , where for any  $\theta$ ,  $\Delta(\theta)$  is the unique  $\Delta$  such that  $\mathcal{B} = \int_k^{k+\Delta} g(y; \theta) dy$ , and  $\theta_0$  satisfies*

$$f(y) = \begin{cases} g(y; \theta_0) & y < k \\ g(y + \Delta(\theta_0); \theta_0) & y > k \end{cases} \quad (14)$$

*Proof.* See Section D. □

The standard approach of fitting a high-order polynomial to  $f_0(y)$  can satisfy the assumptions of Proposition I.2, since polynomial functions are analytic everywhere. Proposition I.2 yields an identification result that can justify an estimation approach similar to one often made in the literature, based on Chetty et al. (2011).<sup>17</sup> However, it requires taking seriously

---

<sup>16</sup>Note that if we had instead assumed that  $f_0^G(y)$  is linear (on the interval  $[G(k), G(k) + \delta^G]$ ), then we simply replace  $f(y)$  by  $f^G(y)$  in the above and let  $G$  be the identity function, which can be readily solved for  $\delta^G$  with the simpler expression  $\delta^G = \mathcal{B}/\frac{1}{2} \{ \lim_{y \uparrow k} f^G(y) + \lim_{y \downarrow k} f^G(y) \}$ .

<sup>17</sup>The estimation technique proposed by Chetty et al. (2011) ignores the shift term  $\Delta(\theta)$  in Equation (14), a limitation discussed by Kleven (2016). This is perhaps less problematic in typical settings where the bunching is somewhat diffuse around the kink, in contrast to the overtime setting in which bunching is exact, and the slope of the density is far from zero near 40. A more robust estimation procedure for parametric bunching designs could be based on iterating on Equation (14) after updating  $\Delta(\theta)$ , until convergence. This presents an interesting topic for future research.

the idea that  $f_0(y) = g(y; \theta_0)$ , treating the approach as parametric rather than as a series approximation to a nonparametric density  $f_0(y)$ . This assumption is very strong. Indeed, assuming that  $g(y; \theta_0)$  follows a polynomial exactly has even more identifying power than is exploited by Proposition I.2. In particular, if we also have that  $f_1(y) = g(y; \theta_1)$  then we could use data on either side of the kink to identify by  $\theta_0$  and  $\theta_1$ , which would allow identification of the average treatment effect with complete treatment effect heterogeneity.

### I.3 Nonparametric approaches with homogeneous treatment effects

The additional assumptions from the preceding section have allowed for point-identification of causal effects under an assumption of homogenous treatment effects. These assumptions have taken the form of parametric restrictions on the density of counterfactual choices  $Y_{0i}$  in the missing region  $[k, k + \Delta]$ : that this density is linear or more generally fits a parametric family of analytic functions. As has been argued in Blomquist and Newey (2017), these parametric assumptions drive all of the identification, an undesirable feature from the standpoint of robustness to departures from them. I now explore some non-parametric assumptions about  $f_0(y)$  that yield bounds on  $\Delta$  in a model with homogeneous treatment effects.

For example, monotonicity of  $f_0(y)$  has been suggested by Blomquist and Newey (2017) as an alternative assumption in the context of the iso-elastic model. A result based on monotonicity that allows heterogeneous treatment effects is presented in Section I.4. However, monotonicity may be restrictive if the density of  $Y_0$  has a mode near the kink point. In this case, local log-concavity of  $f_0(y)$  may be a more attractive assumption (concavity or convexity would be another).<sup>18</sup> Note that log-concavity is a stronger version of the bi-log-concavity assumption used in the main text, but still nests many common parametric distributions such as the uniform, normal, exponential extreme value and logistic. For simplicity, this result assumes homogeneous treatment effects in levels (rather than after applying a function  $G$ ).

**Proposition I.3 (bounds from log-concavity).** *Suppose that  $\Delta_i = \Delta$  and that  $f_0(y)$  is log-concave in the interval  $y \in [k, k + \Delta]$  and continuously differentiable at  $k$  and  $k + \Delta$ . Then, under CONVEX and CHOICE:*

$$\Delta \in [\Delta^L, \Delta^U]$$

where

$$\Delta^U = \mathcal{B} \cdot \frac{\ln(f_+) - \ln(f_-)}{f_+ - f_-} \quad \text{and} \quad \Delta^L = \left( \frac{f_-}{f'_-} - \frac{f_+}{f'_+} \right) \ln \left( \frac{\mathcal{B} + \frac{f_-^2}{f'_-} - \frac{f_+^2}{f'_+}}{\frac{f_-}{f'_-} - \frac{f_+}{f'_+}} \right) + \frac{f_+}{f'_+} \ln f_+ - \frac{f_-}{f'_-} \ln f_-$$

---

<sup>18</sup>Log concavity has previously been assumed as a shape restriction in the context of bunching by Diamond and Persson (2016), though to study the effects of manipulation on other variables, rather than for the effect of incentives on the variable being manipulated.

where  $f'_- := \lim_{y \uparrow k} f'(y)$  and  $f'_+ := \lim_{y \downarrow k} f'(y)$

*Proof.* See Figure 14. Derivation of expressions available by request.  $\square$

Intuition for Proposition I.3 is provided in Figure 14. If  $f_0(y)$  is log convex rather than log-concave in the missing region, then the bounds  $\Delta^L$  and  $\Delta^U$  can simply be swapped. Or, if we suppose that  $f_0$  is *either* log-concave or log-convex locally:  $\Delta \in [\min\{\Delta^U, \Delta^L\}, \max\{\Delta^U, \Delta^L\}]$ .

**Figure 14:** The left and right panels of this figure depict intuition for the lower and upper bounds on  $\Delta$  in Proposition I.3. In both panels, the hatched region is the missing region  $[k, k + \Delta]$  which contains known mass  $\mathcal{B}$ . The function plotted is  $g(y)$ , the logarithm of  $f_0(y)$ . Outside of the missing region, this function is known. Concavity of  $g(y)$  provides both upper and lower bounds for the values of  $g(y)$  inside the missing region, yielding the analytic bounds in Proposition I.3.

## I.4 Alternative identification strategies with heterogeneous treatment effects

An argument made in Saez 2010 and Kleven and Waseem (2013) uses a uniform density assumption to allow heterogeneous treatment in the bunching-design. If a kink is very small, then this might be justified as an approximation given smoothness of  $f(\Delta, y)$ , since  $\Delta_i$  will be “small” for all  $i$ . Below I state an analog of this result in the generalized bunching design framework of this paper. The result will make use of the following Lemma, which states that treatment effects must be positive at the kink:

**Lemma POS (positive treatment effect at the kink).** *Under WARP and CHOICE,  $P(\Delta_i \geq 0 | Y_{0i} = k) = P(\Delta_i \geq 0 | Y_{1i} = k) = 1$ .*

*Proof.* See proof of Lemma B.1, which rules out the events  $Y_{0i} \leq k < Y_{1i}$  and  $Y_{0i} < k \leq Y_{1i}$ .  $\square$

**Proposition I.4 (identification of an ATE under uniform density approximation).**

Let  $\Delta_i$  and  $Y_{0i}$  admit a joint density  $f(\Delta, y)$  that is continuous in  $y$  at  $y = k$ . For each  $\Delta$  assume that  $f(\Delta, Y_0) = f(\Delta, k)$  for all  $Y_0$  in the region  $[k, k + \Delta]$ . Under Assumptions WARP and CHOICE

$$\mathbb{E} [\Delta_i | Y_{0i} = k] \geq \frac{\mathcal{B}}{\lim_{y \uparrow k} f(y)},$$

with equality under CONVEX.

*Proof.* Note that

$$\begin{aligned} \mathcal{B} \leq P(Y_{0i} \in [k, k + \Delta_i]) &= \int_0^\infty d\Delta \int_k^{k+\Delta} dy \cdot f(\Delta, y) = \int_0^\infty f(\Delta, k) \Delta d\Delta \\ &= f_0(k) P(\Delta_i \geq 0 | Y_{0i} = k) \mathbb{E} [\Delta_i | Y_{0i} = k, \Delta \geq 0] \\ &\leq \lim_{y \uparrow k} f(y) \cdot \mathbb{E} [\Delta_i | Y_{0i} = k] \end{aligned}$$

using Lemma POS in the last step. The inequalities are equalities under CONVEX.  $\square$

Lemma SMALL in Appendix A formalizes the idea that the uniform density approximation from Proposition I.4 becomes exact in the limit of a “small” kink.

We can also produce a result based on monotonicity, allowing heterogeneous treatment effects. Let  $\tau_0 := \mathbb{E}[\Delta_i | Y_{0i} = k]$  and  $\tau_1 := \mathbb{E}[\Delta_i | Y_{1i} = k]$ .

**Proposition I.5 (monotonicity with heterogeneous treatment effects).** Assume CONVEX and CHOICE, and suppose the joint density  $f_0(\Delta, y)$  of  $\Delta_i$  and  $Y_{0i}$  and the joint density  $f_1(\Delta, y)$  of  $\Delta_i$  both exist. Suppose first that  $f_0(\Delta, y)$  is weakly increasing on the interval  $y \in [k, k + \Delta]$  for all  $\Delta$  in the support of  $\Delta_i$ . Then

$$\tau_1 \geq \frac{\mathcal{B}}{\lim_{y \downarrow k} f(y)} \quad \text{and} \quad \tau_0 \leq \frac{\mathcal{B}}{\lim_{y \uparrow k} f(y)}$$

Alternatively, if  $f_1(\Delta, y)$  is weakly decreasing on the interval  $y \in [k - \Delta, k]$  for each  $\Delta$ , then

$$\tau_0 \geq \frac{\mathcal{B}}{\lim_{y \uparrow k} f(y)} \quad \text{and} \quad \tau_1 \leq \frac{\mathcal{B}}{\lim_{y \downarrow k} f(y)}$$

*Proof.* Note that  $f_1(\Delta, y) = f_0(\Delta, y + \Delta)$  for any  $y, \Delta$ , and hence  $f_0(y, \Delta)$  is increasing (decreasing) on  $[k, k + \Delta]$  whenever  $f_1(y, \Delta)$  is increasing (decreasing) on  $[k - \Delta, k]$ . Then:

$$\begin{aligned} \mathcal{B} &= \int_0^\infty d\Delta \int_k^{k+\Delta} dy \cdot f_0(\Delta, y) \leq \int_0^\infty \Delta f_0(\Delta, k) d\Delta = f_0(k) \tau_0 \\ \mathcal{B} &= \int_0^\infty d\Delta \int_{k-\Delta}^k dy \cdot f_1(\Delta, y) \geq \int_0^\infty \Delta f_1(\Delta, k) d\Delta = f_1(k) \tau_0 \end{aligned}$$

for example in the first case, where we have used Lemma POS. The reverse case is analogous  $\square$

This result implies that when treatment effects are statistically independent of  $Y_0$  (for example when they are homogenous):  $\Delta_i \perp Y_{0i}$ , we have that  $\mathbb{E}[\Delta_i] = \tau_0 = \tau_1 \in \left[ \frac{\mathcal{B}}{\max\{f_-, f_+\}}, \frac{\mathcal{B}}{\min\{f_-, f_+\}} \right]$ .

Other approaches to identification with heterogeneous treatment effects are possible when the researcher observes covariates  $X_i$  that are unaffected by a counterfactual shift between  $B_1$  and  $B_0$ . For example, assuming that  $\mathbb{E}[X_i|Y_{0i} = y]$  or  $\mathbb{E}[X_i|Y_{1i} = y]$  are Lipschitz continuous with a known constant leads to a lower bound on maximum of  $\tau_0$  and  $\tau_1$  from an observed discontinuity of  $\mathbb{E}[X_i|Y_i = y]$  at  $y = k$ . Another strategy for using covariates would be to model the potential outcomes  $Y_{0i}$  and  $Y_{1i}$  as functions of them. If we are willing to suppose that

$$Y_{0i} = g_0(X_i) + U_{0i} \quad \text{and} \quad Y_{1i} = g_1(X_i) + U_{1i}$$

with  $U_{1i}$  and  $U_{0i}$  each statistically independent of  $X_i$ , then the censoring of the distributions of  $Y_{0i}$  and  $Y_{1i}$  in Lemma B.1 can be “undone”, following the results of Lewbel and Linton (2002).<sup>19</sup> This would allow estimation of the unconditional average treatment effect as well as quantile treatment effects at all levels. However, the assumption that  $U_0$  and  $U_1$  are independent of  $X$  is quite strong.

## I.5 Two bunching design settings from the literature

Below I discuss two examples from the literature that illustrate the general kink bunching design framework described in Section 4. The first is the classic labor supply example, where convexity of preferences arises from increasing opportunity costs of time allocated to labor. In the second example, firms are again the decision makers but now the “running variable”  $y$  is a function of two underlying choice variables  $\mathbf{x}$ .

### Example 1: Labor supply with taxation

Individuals have preferences  $\tilde{u}_i(c, y)$  over consumption  $c$ , and labor earnings  $y$ , where  $\epsilon_i$  is a vector of parameters capturing heterogeneity over the disutility of labor, labor productivity, etc. The agent’s budget constraint is  $c \leq y - B(y)$  where  $B(y)$  is income tax as a function of pre-tax earnings  $y$ .  $\tilde{u}_i(c, y)$  is taken to be strictly quasi-concave in  $(c, y)$  for each  $i$  as the opportunity cost of leisure rises with greater earnings, and monotonically increasing in consumption. Define  $z = y - c$  to be tax liability, and let  $u_i(z, y) = \tilde{u}_i(y - z, y)$  which is monotonically decreasing in tax. Individuals now choose a value of  $y$  (e.g. by adjusting hours of work, number of jobs, or misreporting) given a progressive tax schedule  $B_k(y) = \tau_0 y + 1(y \geq k)(\tau_1 - \tau_0)(y - k)$ , with the kink arising from an increase in marginal tax rates

---

<sup>19</sup>Lewbel and Linton (2002) establish identification of  $g(x)$  and  $F_U(u)$  in a model where the econometrician observes censored observations of  $Y = g(X) + U$ . Given knowledge of the distribution of  $X$ , the estimated marginal distributions of  $U_1$  and  $U_2$ , and the estimated function  $g(x)$  the researcher could estimate the distributions  $F_1(y) = P(Y_{1i} \leq y)$  and  $F_0(y) = P(Y_{0i} \leq y)$  by deconvolution, and then estimate causal effects.

from  $\tau_0$  to  $\tau_1 > \tau_0$  at  $y = k$ . The budget functions are  $B_0(y) = \tau_0 y$ ,  $B_1(y) = \tau_1 y - (\tau_1 - \tau_0)k$ , and the kinked budget constraint can be written  $z \geq B_k(y) = \max\{B_0(y), B_1(y)\}$ .

### Example 2: Minimum tax schemes

Best et al. (2015) study a feature of corporate taxation in Pakistan in which firms pay the maximum of a tax on output and a tax on reported profits:

$$B(r, \hat{w}) = \max\{\tau_\pi(r - \hat{w}), \tau_r r\}$$

where  $r$  is firm revenue,  $\hat{w}$  is reported costs, and  $\tau_r < \tau_\pi$ . Under the profit tax, firms have incentive to reduce their tax liability by inflating the value  $\hat{w}$  above their true costs of production  $w_i(r)$ . One can write tax liability as a piecewise function in which the tax regime depends on reported profits as a fraction of output:  $y = \frac{r - \hat{w}}{r} = 1 - \frac{\hat{w}}{r}$ :

$$B(r, \hat{w}) = \begin{cases} \tau_r r & \text{if } y \leq \tau_r / \tau_\pi \\ \tau_\pi(r - \hat{w}) & \text{if } y > \tau_r / \tau_\pi \end{cases}$$

This function has a “kink” in both  $r$  and  $\hat{w}$  when  $y(r, \hat{w}) = k = \tau_r / \tau_\pi$ . In this setting,  $B_0(r, \hat{w}) = \tau_r r$ , corresponding to a tax on output while  $B_1(r, \hat{w}) = \tau_\pi(r - \hat{w})$  describes a tax on (reported) profits. Both functions are linear, and hence weakly convex, in the vector  $(r, \hat{w})$ . The functions  $B_{0i}$ ,  $B_{1i}$  and  $y_i$  are all common across firms.

Assume that firm  $i$  chooses the pair  $\mathbf{x} = (r, \hat{w})$  according to preferences  $u_i(z, \mathbf{x})$ , which are strictly decreasing in tax liability  $z$  and strictly quasiconcave in  $(z, r, \hat{w})$ . In Best et al. (2015), preferences are for example taken to be in a baseline model:

$$u_i(z, r, \hat{w}) = r - w_i(r) - g_i(\hat{w} - w_i(r)) - z \quad (15)$$

where  $g_i(\cdot)$  represents costs of tax evasion by misreporting costs. This specification of  $u_i(z, r, \hat{w})$  is strictly quasi-concave provided that the production and evasion cost functions  $w_i(\cdot)$  and  $g_i(\cdot)$  are strictly convex.

With such preferences, the presence of the minimum tax kink can be expected to lead to a firm response among both margins of  $\mathbf{x}$ :  $r$  and  $\hat{w}$ . In particular, consider a linear

approximation to  $\Delta_i = Y_i(0) - Y_i(1)$  for a buncher with  $Y_{0i} \approx k$ , keeping the  $i$  implicit:

$$\begin{aligned}
\Delta &\approx \frac{dy(r, \hat{w})}{\hat{w}} \Big|_{(r_0, \hat{w}_0)} \Delta_{\hat{w}} + \frac{dy(r, \hat{w})}{r} \Big|_{(r_0, \hat{w}_0)} \Delta_r \\
&= \frac{\hat{w}_0}{r_0^2} \Delta_r - \frac{1}{r_0} (\Delta_{w(r)} + \Delta_{(\hat{w}-w(r))}) \\
&\approx \frac{\hat{w}_0}{r_0^2} \Delta_r - \frac{1}{r_0} (w'(r_0) \Delta_{ri} + \Delta_{(\hat{w}-w(r))}) \\
&= \frac{1}{r_0} \{(1 - Y_0 - w'(r_0)) \Delta_r \Delta_{\hat{w}}\} \approx \frac{1}{r} \{-k \Delta_r - \Delta_{(\hat{w}-w)}\} \\
&\approx \frac{1}{r_0} \left\{ -\frac{\tau_r}{\tau_\pi} \cdot r \epsilon^r \frac{d(1 - \tau_E)}{\tau_E} - \Delta_{\hat{w}i} \right\} = \frac{\tau_r^2}{\tau_\pi} \epsilon^r - \frac{\Delta_{(\hat{w}-w)}}{r_0} \tag{16}
\end{aligned}$$

where  $\epsilon^r$  is the elasticity of firm revenue with respect to the net of effective tax rate  $1 - \tau_E$ . In this case, when crossing from the output to reported profits regime  $\frac{d(1 - \tau_E)}{\tau_E} = -\tau_r$ , implying the final expression (see Best et al. 2015 for definition of  $\tau_E$ ). We have also used the optimality condition that  $w'(r_0) = 1$ . Expression (16) shows that the response to the minimum tax kink is almost entirely driven by a response on the difference between reported and actual costs:  $\hat{w}_i - w_i(r)$ . This is because  $\tau_r$  is less than 1%, so the first term ends up not contributing meaningfully in practice (it scales as the square of  $\tau_r$ ). In this empirical setting, it is thus possible to interpret the bunching response as a response to one of the components of  $\mathbf{x}$ , despite  $\mathbf{x}$  being a vector.

We can also situate the setting of Best et al. (2015) in terms of a continuum of cost functions, as in Section B.7. In particular, let  $\rho \in [0, 1]$  and define

$$B(r, \hat{w}; \rho, k) = \frac{\tau_r}{1 - \rho(1 - k)} (y - \rho c)$$

Then  $B_0(r, \hat{w}) = B(r, \hat{w}; 0)$  and  $B_1(r, \hat{w}; \tau_r/\tau_\pi) = B(r, \hat{w}; 1, \tau_r/\tau_\pi)$ . It can be verified that for any  $\rho' > \rho$  and  $k$ ,  $B(r, \hat{w}; \rho', k) > B(r, \hat{w}; \rho, k)$  iff  $y_i(r, \hat{w}) > k$ , with equality when  $y_i(r, \hat{w}) = k$ . The path from  $\rho_0 = 0$  to  $\rho_1 = 1$  passes through a continuum of tax policies in which the tax base gradually incorporates reported costs, while the tax rate on that tax base also increases continuously with  $\rho$ .

## J Further proofs

### J.1 Proof of Propositions B.1 and B.2

Consider Proposition B.1. Item i) in the proof of Lemma B.1 establishes that under CHOICE and WARP  $Y_i = k$  implies  $Y_{1i} \leq k \leq Y_{0i}$ , since taking contrapositives we have that  $(Y_i \geq k \text{ and } Y_i \leq k)$  implies  $Y_{1i} \leq k \leq Y_{0i}$ . We have also seen from item ii) that under CHOICE and CONVEX  $Y_{1i} \leq k \leq Y_{0i}$  also implies  $Y_i = k$ , thus  $Y_{1i} \leq k \leq Y_{0i}$  and  $Y_i = k$  are equivalent.

Note that by adding  $\Delta_i = Y_{0i} - Y_{1i}$  to both sides of the inequality  $Y_{1i} \leq k$ , we have that  $Y_{0i} \leq k + \Delta_i$ . Combining with the other inequality that  $Y_{0i} \geq k$ , we can thus rewrite the event  $Y_{1i} \leq k \leq Y_{0i}$  as  $Y_{0i} \in [k, k + \Delta_i]$  (or equivalently to  $Y_{1i} \in [k - \Delta_i, k]$ ). We thus have that  $\mathcal{B} \leq P(Y_{0i} \in [k, k + \Delta])$  under CHOICE and WARP, and that  $\mathcal{B} = P(Y_i = k) = P(Y_{1i} \leq k \leq Y_{0i})$  under CHOICE and CONVEX.

Now consider Proposition B.2. By item i) in the proof of Proposition B.1, we have that under WARP and CHOICE  $Y_{0i} \leq k \implies Y_i = Y_{0i}$ . Thus, for any  $\delta > 0$  and  $y < k$ :  $Y_{0i} \in [y - \delta, y]$  implies that  $Y_i \in [y - \delta, y]$  and hence  $P(Y_{0i} \in [y - \delta, y]) \leq P(Y_i \in [y - \delta, y])$ . This implies that  $f_0(y) - f(y) = \lim_{\delta \downarrow 0} \frac{P(Y_{0i} \in [y - \delta, y]) - P(Y_i \in [y - \delta, y])}{\delta} \leq 0$ , i.e. that  $f(y) \geq f_0(y)$ . An analogous argument holds for  $Y_1$ , where we consider the event  $Y_{1i} \in [y, y + \delta]$  any  $y > k$ . Under CONVEX instead of WARP, the inequalities are all equalities, by Lemma B.1.

## J.2 Proof of Lemma B.2

Let  $\Delta_i^k(\rho, \rho') := Y_i(\rho, k) - Y_i(\rho', k)$  for any  $\rho, \rho' \in [\rho_0, \rho_1]$  and value of  $k$ .

**Assumption SMOOTH (regularity conditions).** *The following hold:*

1.  $P(\Delta_i^k(\rho, \rho') \leq \Delta, Y_i(\rho, k) \leq y)$  is twice continuously differentiable at all  $(\Delta, y) \neq (0, k^*)$ , for any  $\rho, \rho' \in [\rho_0, \rho_1]$  and  $k$ .
2.  $Y_i(\rho, k) = Y(\rho, k, \epsilon_i)$ , where  $\epsilon_i$  has compact support  $E \subset \mathbb{R}^m$  for some  $m$ .  $Y(\cdot, k, \cdot)$  is continuously differentiable on all of  $[\rho_0, \rho_1] \times E$ , for every  $k$ .
3. there possibly exists a set  $\mathcal{K}^* \subset E$  such that  $Y(\rho, k, \epsilon) = k^*$  for all  $\rho \in [\rho_0, \rho_1]$  and  $\epsilon \in \mathcal{K}^*$ . The quantity  $\mathbb{E} \left[ \frac{\partial Y_i(\rho, k)}{\partial \rho} \middle| Y_i(\rho, k) = y, \epsilon_i \notin \mathcal{K}^* \right]$  is continuously differentiable in  $y$  for all  $y$  including  $k^*$ .

In the remainder of this proof I keep  $k$  be implicit in the functions  $Y_i(\rho, k)$  and  $\Delta_i^k(\rho, \rho')$ , as it will remained fixed. Item 1 of SMOOTH excludes the point  $(0, k^*)$  on the basis that we may expect point masses at  $Y_i(\rho) = k^*$ , as in the overtime setting. Following Section 4, item 3 imposes that all such “counterfactual bunchers” have zero treatment effects, while also introducing a further condition that will be used later in Lemma B.3. Let  $K_i^*$  be an indicator for  $\epsilon_i \in \mathcal{K}^*$  and denote  $p = P(K_i^* = 1)$ . Item 1 implies that the density  $f_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, y)$  is continuous in  $y$  whenever  $y \neq k^*$  or  $\Delta \neq 0$ , so I define  $f_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, k^*) = \lim_{y \rightarrow k^*} f_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, y)$  for any  $\rho, \rho'$  and  $\Delta$ . Similarly, we can define the marginal density  $f_\rho(y)$  of  $Y_i(\rho)$  at  $k^*$  to be  $\lim_{y \rightarrow k^*} f_\rho(y)$  for any  $\rho$ .

By item 1 of Assumption SMOOTH, the marginal  $F_\rho(y) := P(Y_i(\rho) \leq y)$  is differentiable away from  $y = k$  with derivative  $f_\rho(y)$ . From the proof of Theorem B.1 it follows that

$\mathcal{B} \leq F_{\rho_1}(k) - F_{\rho_0}(k) + p(k)$  with equality under CONVEX, and thus:

$$\begin{aligned} \mathcal{B} - p(k) &\leq F_{\rho_1}(k) - F_{\rho_0}(k) = \int_{\rho_0}^{\rho_1} \frac{d}{d\rho} F_{\rho}(k) d\rho = \int_{\rho_0}^{\rho_1} \lim_{\delta \downarrow 0} \frac{F_{\rho+\delta}(k) - F_{\rho}(k)}{\delta} d\rho \\ &= \int_{\rho_1}^{\rho_0} \lim_{\delta \downarrow 0} \frac{P(Y_i(\rho + \delta) \leq k \leq Y_i(\rho)) - p(k)}{\delta} d\rho = \int_{\rho_1}^{\rho_0} f_{\rho}(k) \mathbb{E} \left[ -\frac{Y_i(\rho)}{d\rho} \middle| Y_i(\rho) = k \right] d\rho \end{aligned}$$

where the third equality applies the identity  $1 = P(Y_{0i} \leq k) + P(Y_i(\rho) \leq k \leq Y_i(\rho + \delta)) + P(Y_{1i} > k)$  under CHOICE and WARP (this follows from item i) of the proof of Lemma B.1) to the pair of choice constraints  $B(\rho)$  and  $B(\rho + \delta)$ , noting that  $P(Y_i(\rho) < k) = F_{\rho}(k) - p(k)$ . The final equality uses Lemma SMALL.

### J.3 Proof of Lemma SMALL

Throughout this proof we let  $f_W$  denote the density of a generic random variable or random vector  $W_i$ , if it exists. Write  $\Delta_i(\rho, \rho') = \Delta_i(\rho, \rho', \epsilon_i)$  where  $\Delta_i(\rho, \rho', \epsilon) := Y(\rho, \epsilon) - Y(\rho', \epsilon)$ .

$$\begin{aligned} \lim_{\rho' \downarrow \rho} \frac{P(Y_i(\rho) \leq k \leq Y_i(\rho')) - p(k)}{\rho' - \rho} &= \lim_{\rho' \downarrow \rho} \frac{P(Y_i(\rho) \in [k, k + \Delta(\rho, \rho')_i]) - p(k)}{\rho' - \rho} \\ &= \lim_{\rho' \downarrow \rho} \frac{P(Y_i(\rho) \in (k, k + \Delta(\rho, \rho')_i])}{\rho' - \rho} \\ &= \lim_{\rho' \downarrow \rho} \frac{1}{\rho' - \rho} \int_0^{\infty} d\Delta \int_k^{k+\Delta} dy \cdot f_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, y) \\ &= \lim_{\rho' \downarrow \rho} \int_0^{\infty} d\Delta \int_k^{k+\Delta} dy \cdot \frac{f_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, k) + (y - k)r_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, k, y)}{\rho' - \rho} \end{aligned} \tag{17}$$

where we have used that by item 1 the joint density of  $\Delta_i(\rho, \rho')$  and  $Y_i(\rho)$  exists for any  $\rho, \rho'$  and is differentiable and  $r_{\Delta(\rho, \rho'), Y(\rho)}$  is a first-order Taylor remainder term satisfying

$$\lim_{y \downarrow k} |r_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, y)| = |r_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, k)| = 0$$

for any  $\Delta$ .

I now show that the whole term corresponding to this remainder is zero. First, note that:

$$\begin{aligned} \left| \lim_{\rho' \downarrow \rho} \int_0^{\infty} d\Delta \int_k^{k+\Delta} dy \cdot \frac{(y - k)r_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, y)}{\rho' - \rho} \right| &= \lim_{\rho' \downarrow \rho} \left| \int_0^{\infty} d\Delta \int_k^{k+\Delta} dy \cdot \frac{(y - k)r_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, y)}{\rho' - \rho} \right| \\ &\leq \lim_{\rho' \downarrow \rho} \int_0^{\infty} d\Delta \int_k^{k+\Delta} dy \cdot \left| \frac{(y - k)r_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, y)}{\rho' - \rho} \right| \\ &\leq \lim_{\rho' \downarrow \rho} \int_0^{\infty} d\Delta \frac{\Delta}{\rho' - \rho} \int_k^{k+\Delta} dy \cdot |r_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, y)| \end{aligned}$$

where I've used continuity of the absolute value function and the Minkowski inequality. Define  $\xi(\rho, \rho') = \sup_{\epsilon \in E} \Delta(\rho, \rho', \epsilon)$ . The strategy will be show that  $\lim_{\rho' \downarrow \rho} \xi(\rho, \rho') = 0$ , and then since  $r_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, y) = 0$  for any  $\Delta > \xi(\rho, \rho')$  and all  $y$  (since the marginal density

$f_{\Delta(\rho, \rho')}(\Delta)$  would be zero for such  $\Delta$ ). With  $\xi(\rho, \rho')$  so-defined:

$$\begin{aligned} \text{RHS of above} &\leq \lim_{\rho' \downarrow \rho} \int_0^{\xi(\rho, \rho')} d\Delta \frac{\xi(\rho, \rho')}{\rho' - \rho} \int_k^{k+\xi(\rho, \rho')} dy \cdot |r_{\Delta_i(\rho, \rho'), Y_i(\rho)}(\Delta, y)| \\ &= \lim_{\rho' \downarrow \rho} \frac{\xi(\rho, \rho')}{\rho' - \rho} \cdot \lim_{\rho' \downarrow \rho} \int_0^{\xi(\rho, \rho')} d\Delta \int_0^{\xi(\rho, \rho')} dy \cdot |r_{\Delta_i(\rho, \rho'), Y_i(\rho)}(\Delta, k+y)| \quad (18) \end{aligned}$$

where in the second step I have assumed that each limit exists (this will be demonstrated below). Let us first consider the inner integral of the above:  $\int_k^{k+\xi(\rho, \rho')} dy \cdot |r_{\Delta_i(\rho, \rho'), Y_i(\rho)}(\Delta, y)|$ , for any  $\Delta$ . Supposing that  $\lim_{\rho' \downarrow \rho} \xi(\rho, \rho') = 0$ , it follows that this inner integral evaluates to zero, by the Leibniz rule and using that  $r_{\Delta_i(\rho, \rho'), Y_i(\rho)}(\Delta, k) = 0$ . Thus the entire second limit is equal to zero.

Now I prove that  $\lim_{\rho' \downarrow \rho} \xi(\rho, \rho') = 0$  and that  $\lim_{\rho' \downarrow \rho} \frac{\xi(\rho, \rho')}{\rho' - \rho}$  exists. First, note that continuous differentiability of  $Y(\rho, \epsilon_i)$  implies  $Y_i(\rho)$  is continuous for each  $i$  so  $\lim_{\rho' \downarrow \rho} \Delta_i(\rho, \rho') = 0$  point-wise in  $\epsilon$ . We seek to turn this point-wise convergence into uniform convergence over  $\epsilon$ , i.e. that  $\lim_{\rho' \downarrow \rho} \sup_{\epsilon \in E} \Delta(\rho, \rho', \epsilon) = \sup_{\epsilon \in E} \lim_{\rho' \downarrow \rho} \Delta(\rho, \rho', \epsilon) = \sup_{\epsilon \in E} 0 = 0$ . The strategy will be to use equicontinuity of the sequence and compactness of  $E$ . Consider any such sequence  $\rho_n \xrightarrow{n} \rho$  from above, and let  $f_n(\epsilon) := Y(\rho, \epsilon) - Y(\rho_n, \epsilon)$  and  $f(\epsilon) = \lim_{n \rightarrow \infty} f_n(\epsilon) = 0$ . Equicontinuity of the sequence  $f_n(\epsilon)$  says that for any  $\epsilon, \epsilon' \in E$  and  $e > 0$ , there exists a  $\delta > 0$  such that  $\|\epsilon - \epsilon'\| < \delta \implies |f_n(\epsilon) - f_n(\epsilon')| < e$ .

This follows from continuous differentiability of  $Y(\rho, \epsilon)$ . Let  $M = \sup_{\rho \in [\rho_0, \rho_1], \epsilon \in E} |\nabla_{\rho, \epsilon} Y(\rho, \epsilon)|$ .  $M$  exists and is finite given continuity of the gradient and compactness of  $[\rho_0, \rho_1] \times E$ . Then, for any two points  $\epsilon, \epsilon' \in E$  and any  $\rho \in [\rho_0, \rho_1]$ :

$$|Y(\rho, \epsilon) - Y(\rho, \epsilon')| = \left| \int_{\epsilon'}^{\epsilon} \nabla_{\epsilon} Y(\rho, \epsilon) \cdot d\epsilon \right| \leq \int_{\epsilon'}^{\epsilon} |\nabla_{\epsilon} Y(\rho, \epsilon) \cdot d\epsilon| \leq M \int_{\epsilon'}^{\epsilon} \|d\epsilon\| \leq M \|\epsilon - \epsilon'\|$$

where  $d\epsilon$  is any path from  $\epsilon$  to  $\epsilon'$  and I have used the definition of  $M$  and Cauchy-Schwarz in the second inequality. The existence of a uniform Lipschitz constant  $M$  for  $Y(\rho, \epsilon)$  implies a uniform equicontinuity of  $Y(\rho, \epsilon)$  of the form that for any  $e > 0$  and  $\epsilon, \epsilon' \in E$ , there exists a  $\delta > 0$  such that  $\|\epsilon - \epsilon'\| < \delta \implies \sup_{\rho \in [\rho_0, \rho_1]} |Y(\rho, \epsilon) - Y(\rho, \epsilon')| < e/2$ , since we can simply take  $\delta = e/(2M)$ . This in turn implies that whenever  $\|\epsilon - \epsilon'\| < \delta$ :

$$\begin{aligned} |Y(\rho, \epsilon) - Y(\rho_n, \epsilon) - \{Y(\rho, \epsilon') - Y(\rho_n, \epsilon')\}| &= |Y(\rho, \epsilon) - Y(\rho, \epsilon') - \{Y(\rho_n, \epsilon) - Y(\rho_n, \epsilon')\}| \\ &\leq |Y(\rho, \epsilon) - Y(\rho, \epsilon')| + |Y(\rho_n, \epsilon) - Y(\rho_n, \epsilon')| \leq e, \end{aligned}$$

our desired result. Together with compactness of  $E$ , equicontinuity implies that  $\lim_{n \rightarrow \infty} \sup_{\epsilon \in E} f_n(\epsilon) = \sup_{\epsilon \in E} \lim_{n \rightarrow \infty} f_n(\epsilon) = 0$ .

We apply an analogous argument for  $\lim_{\rho' \downarrow \rho} \frac{\xi(\rho, \rho')}{\rho' - \rho}$ , where now  $f_n(\epsilon) = \frac{Y(\rho, \epsilon) - Y(\rho_n, \epsilon)}{\rho_n - \rho}$ . For this case it's easier to work directly with the function  $\frac{Y(\rho, \epsilon) - Y(\rho_n, \epsilon)}{\rho_n - \rho}$ , showing that it is Lipschitz

in deviations of  $\epsilon$  uniformly over  $n \in \mathbb{N}, \epsilon \in E$ .

$$\begin{aligned} \left| \frac{Y(\rho, \epsilon) - Y(\rho_n, \epsilon)}{\rho_n - \rho} - \frac{Y(\rho, \epsilon') - Y(\rho_n, \epsilon')}{\rho_n - \rho} \right| &= \frac{1}{\rho_n - \rho} \left| \int_{\epsilon'}^{\epsilon} \nabla_{\epsilon} Y(\rho, \epsilon) \cdot d\epsilon - \int_{\epsilon'}^{\epsilon} \nabla_{\epsilon} Y(\rho_n, \epsilon) \cdot d\epsilon \right| \\ &\leq \frac{1}{\rho_n - \rho} \left( \left| \int_{\epsilon'}^{\epsilon} \nabla_{\epsilon} Y(\rho, \epsilon) \cdot d\epsilon \right| + \left| \int_{\epsilon'}^{\epsilon} \nabla_{\epsilon} Y(\rho_n, \epsilon) \cdot d\epsilon \right| \right) \\ &\leq \frac{2M}{\rho_n - \rho} \int_{\epsilon'}^{\epsilon} \|d\epsilon\| \leq \frac{2M}{\rho_n - \rho} \|\epsilon - \epsilon'\| \end{aligned}$$

This implies equicontinuity of  $\frac{Y(\rho, \epsilon) - Y(\rho_n, \epsilon)}{\rho_n - \rho}$  with the choice  $\delta = e(\rho_n - \rho)/(2M)$ . As before, equicontinuity and compactness of  $E$  allow us to interchange the limit and the supremum, and thus:

$$\begin{aligned} \lim_{n \rightarrow \infty} \frac{\xi(\rho, \rho_n)}{\rho_n - \rho} &= \lim_{n \rightarrow \infty} \frac{\sup_{\epsilon \in E} \{Y(\rho, \epsilon) - Y(\rho_n, \epsilon)\}}{\rho_n - \rho} = \lim_{n \rightarrow \infty} \sup_{\epsilon \in E} \frac{Y(\rho, \epsilon) - Y(\rho_n, \epsilon)}{\rho_n - \rho} \\ &= \sup_{\epsilon \in E} \lim_{n \rightarrow \infty} \frac{Y(\rho, \epsilon) - Y(\rho_n, \epsilon)}{\rho_n - \rho} = \sup_{\epsilon \in E} \frac{\partial Y(\rho, \epsilon)}{\partial \rho} := M' < \infty \end{aligned}$$

where finiteness of  $M'$  follows from it being defined as the supremum of a continuous function over a compact set. This establishes that the first limit in Eq. (18) exists and is finite, completing the proof that it evaluates to zero.

Given that the second term in Eq. (17) is zero, we can simplify the remaining term as:

$$\begin{aligned} \lim_{\rho' \downarrow \rho} \frac{P(Y_i(\rho) \leq k \leq Y_i(\rho')) - p(k)}{\rho' - \rho} &= \lim_{\rho' \downarrow \rho} \frac{1}{\rho' - \rho} \int_0^{\infty} f_{\Delta(\rho, \rho'), Y(\rho)}(\Delta, k) \Delta d\Delta \\ &= f_{\rho}(k) \lim_{\rho' \downarrow \rho} \frac{1}{\rho' - \rho} P(\Delta_i(\rho, \rho') \geq 0 | Y_i(\rho) = k) \cdot \mathbb{E} [\Delta_i(\rho, \rho') | Y_i(\rho) = k, \Delta_i(\rho, \rho') \geq 0] \\ &= f_{\rho}(k)(k) \lim_{\rho' \downarrow \rho} \frac{1}{\rho' - \rho} \mathbb{E} [\Delta_i(\rho, \rho') | Y_i(\rho) = k, \Delta_i(\rho, \rho')] = f_{\rho}(k)(k) \mathbb{E} \left[ \lim_{\rho' \downarrow \rho} \frac{\Delta_i(\rho, \rho')}{\rho' - \rho} \middle| Y_i(\rho) = k \right] \\ &= f_{\rho}(k) \mathbb{E} \left[ -\frac{Y_i(\rho)}{d\rho} \middle| Y_i(\rho) = k \right] \end{aligned}$$

where I have used that treatment effects must be positive at the kink (see Lemma POS in Appendix I.4) and then the dominated convergence theorem. To see that we may use it, note that  $\frac{dY_i(\rho)}{d\rho} = \frac{\partial Y(\rho, \epsilon_i)}{\partial \rho} < M$  uniformly over all  $\epsilon_i \in E$ , and  $\mathbb{E}[M | Y_i(\rho) = k] = M < \infty$ .

## J.4 Proof of Proposition F.1

Note: this proof follows the notation of  $Y_i$  from Appendix B, rather than  $h_{1it}$  from Appendix F and the main text. Begin with the following observations:

- $(Y < k) \implies (Y_0 = Y)$  and  $(Y > k) \implies (Y_1 = Y)$  both follow from convexity of preferences, and linearity of the cost functions  $B_1$  and  $B_0$ . From these two it also follows that  $(Y_1 \leq k \leq Y_0) \implies (Y = k)$ . See proof of Theorem B.1, which treats this case.

- For firm-choosers:  $(Y_0 < k) \implies (Y = Y_0)$ , since the cost function  $B_0$  coincides with  $B_k$  for  $y \leq k$ , and is higher otherwise. Similarly  $(Y_1 > k) \implies (Y = Y_1)$ . Together these also imply that  $(Y = k) \implies (Y_1 \leq k \leq Y_0)$ .
- By analogous logic, for worker-choosers:  $(Y_0 \geq k) \implies (Y = Y_1)$ , and  $(Y_1 \leq k) \implies (Y = Y_0)$  using that their utility functions are strictly increasing in  $c$ . Together these also imply that  $Y_1 \leq k \leq Y_0$  can only occur if  $Y_0 = Y_1 = k$ .

Now consider the claims of the Proposition:

- $P(Y_{it} = k \text{ and } K_{it}^* = 0) = P(Y_{1it} \leq 40 \leq Y_{0it} \text{ and } K_{it}^* = 0 \text{ and } W_{it} = 0)$
- $\lim_{y \uparrow 40} f(y) = P(W_{it} = 0) \lim_{y \uparrow 40} f_{0|W=0}(y)$
- $\lim_{y \downarrow 40} f(y) = P(W_{it} = 0) \lim_{y \downarrow 40} f_{1|W=0}(y)$

First claim:

$$\begin{aligned} P(Y_{it} = k \text{ and } K_{it}^* = 0) &= P(Y_{it} = k \text{ and } K_{it}^* = 0 \text{ and } W_{it} = 0) + P(Y_{it} = k \text{ and } K_{it}^* = 0 \text{ and } W_{it} = 1) \\ &= P(Y_{1it} \leq 40 \leq Y_{0it} \text{ and } K_{it}^* = 0 \text{ and } W_{it} = 0) + 0 \end{aligned}$$

where for the first term I've used that when  $W_{it} = 0$ ,  $(Y_{it} = k) \iff (Y_{1it} \leq 40 \leq Y_{0it})$  following Theorem B.1. For the second, I've used that by the absolute continuity assumption:  $P(Y_{0it} = k \text{ or } Y_{1it} = k | K_{it}^* = 0) = 0$ , so:

$$\begin{aligned} P(Y_{it} = k \text{ and } K_{it}^* = 0) &= P(Y_{it} = k \text{ and } K_{it}^* = 0 \text{ and } W_{it} = 1 \text{ and } Y_{0it} < k) \\ &\quad + P(Y_{it} = k \text{ and } K_{it}^* = 0 \text{ and } W_{it} = 1 \text{ and } Y_{0it} > k) \\ &= P(Y_{it} = k \text{ and } K_{it}^* = 0 \text{ and } W_{it} = 1 \text{ and } Y_{0it} < k \text{ and } Y_{1it} = k) \\ &\quad + P(Y_{it} = k \text{ and } K_{it}^* = 0 \text{ and } W_{it} = 1 \text{ and } Y_{0it} > k \text{ and } Y_{1it} = k) \\ &= 0 + 0 = 0 \end{aligned}$$

where I've used that  $W_{it} = 1$  and  $Y_{0it} < k$  and implies that  $Y_{it} = Y_{0it}$  if  $Y_{1it} < k$ , and  $Y_{it} \in \{Y_{0it}, Y_{1it}\}$  if  $Y_{1it} > k$  to eliminate the first term. The second term uses that  $Y_1 \leq k \leq Y_0$  can only occur when  $Y_0 = Y_1 = k$ .

Second claim:

$$\begin{aligned} \lim_{y \uparrow k} f(y) &= \lim_{y \uparrow k} \frac{d}{dy} P(Y_{it} \leq y) \\ &= \lim_{y \uparrow k} \frac{d}{dy} P(Y_{it} \leq y \text{ and } W_{it} = 0) + \lim_{y \uparrow k} \frac{d}{dy} P(Y_{it} \leq y \text{ and } W_{it} = 1) \end{aligned}$$

The first term is equal to  $P(W_{it} = 0) \lim_{y \uparrow k} f_{0|W=0}(y)$ , and I now show that the second is equal to zero:

$$\begin{aligned} \lim_{y \uparrow k} \frac{d}{dy} P(Y_{it} \leq y \text{ and } W_{it} = 1) \\ &= \lim_{y \uparrow k} \frac{d}{dy} P(Y_{0it} \leq y \text{ and } Y_{it} = Y_{0it} \text{ and } W_{it} = 1) \\ &= \lim_{y \uparrow k} \frac{d}{dy} P(Y_{0it} \leq y \text{ and } \{u(B_0(Y_{0it}), Y_{0it}) \geq u_{it}(B_1(y), y) \text{ for all } y > k\} \text{ and } W_{it} = 1) \end{aligned}$$

For  $it$ 's utility under  $B_k$  at  $Y_{0it}$  to be greater than that attainable at any  $y > k$ , the indifference curve  $IC_{0it}$  passing through  $Y_{0it}$  must lie above  $B_{1it}(y) = w_{it}y + \frac{w_{it}}{2}(y - k)$  for all  $y > k$ . Using that  $IC_{0it}$  passes through the point  $(w_{it}Y_{0it}, Y_{0it})$  with derivative  $w_{it}$  there (by the first-order condition for an optimum), we may write it as

$$\begin{aligned} IC_{0it}(y) &= w_{it}Y_{0it} + \int_{Y_{0it}}^y IC'_{0it}(y') dy' = w_{it}Y_{0it} + \int_{Y_{0it}}^y \left\{ w_{it} + \int_{Y_{0it}}^{y'} IC''_{0it}(y'') dy'' \right\} dy' \\ &\leq w_{it}y + \int_{Y_{0it}}^y M(y' - Y_{0it}) dy' = w_{it}y + \frac{1}{2}(y - Y_{0it})^2 M_{it} \end{aligned}$$

using that  $IC_{0it}$  is twice differentiable. Now  $IC_{0it}(y) \geq B_{1it}(y)$  for  $y > k$  implies that

$$\frac{w_{it}}{M_{it}}(y - k) \leq (y - Y_{0it})^2$$

Taking for example  $y = 80 - Y_{0it}$ , such that  $y - k = y - Y_{0it}$ , we have that  $Y_{0it} \leq k - \frac{w_{it}}{M_{it}}$ . Thus:

$$\begin{aligned} \lim_{y \uparrow k} \frac{d}{dy} P(Y_{it} \leq y \text{ and } Y_{it} > Y_{0it} \text{ and } W_{it} = 1) \\ &\leq \lim_{y \uparrow k} \lim_{\delta \downarrow 0} \frac{1}{\delta} P(Y_{0it} \in (y - \delta, y] \text{ and } Y_{0it} \leq k - \frac{w_{it}}{M_{it}} \text{ and } W_{it} = 1) \\ &\leq \lim_{y \uparrow k} \lim_{\delta \downarrow 0} \frac{1}{\delta} P(Y_{0it} \in (y - \delta, y] \text{ and } \frac{w_{it}}{M_{it}} \leq k - y + \delta \text{ and } W_{it} = 1) \\ &\leq \lim_{y \uparrow k} \lim_{\delta \downarrow 0} \frac{1}{\delta} P\left(\frac{w_{it}}{M_{it}} \leq k - y + \delta \text{ and } W_{it} = 1\right) \\ &\leq \lim_{\delta \downarrow 0} \frac{1}{\delta} P\left(\frac{w_{it}}{M_{it}} \leq \delta \text{ and } W_{it} = 1\right) \\ &= f_{w/m|W=1}(0) = 0 \end{aligned}$$

where we may interchange the limits given that  $\frac{w_{it}}{M_{it}}$  conditional on  $W_{it} = 1$  admits a density  $f_{w/m|W=1}$  that is bounded in a neighborhood around 0. This, and that  $f_{w/m|W=1}(0) = 0$  follows from the assumption that the distribution of  $M_{it}/w_{it}$  is bounded.

We have now proved the second claim, that  $\lim_{y \uparrow k} f(y) = P(W_{it} = 0) \lim_{y \uparrow k} f_{0|W=0}(y)$ .

Third claim: Analogous logic to the second claim, using the bounded  $2^{nd}$  derivative of  $IC_{1it}$ .

## J.5 Proof of Theorem 1\*

Note: this proof follows the notation of  $Y_i$  from Appendix B, rather than  $h_{it}$  from Appendix F and the main text. Let  $T_i = 1$  be a shorthand for firm-choosers who are not counterfactual bunchers, i.e. the event  $K_{it}^* = 0$  and  $W_{it} = 0$ .

By Theorem 1 of Dömbgen et al., 2017: for  $d \in \{0, 1\}$  and any  $t$ , bi-log concavity implies that:

$$1 - (1 - F_{d|T=1}(k))e^{-\frac{f_{d|T=1}(k)}{1-F_{d|T=1}(k)}t} \leq F_{d|T=1}(k+t) \leq F_{d|T=1}(k)e^{\frac{f_{d|T=1}(k)}{F_{d|T=1}(k)}t}$$

Defining  $u = F_{0|T=1}(k+t)$ , we can use the substitution  $t = Q_{0|T=1}(u) - k$  to translate the above into bounds on the conditional quantile function of  $Y_{0i}$ , evaluated at  $u$ :

$$\frac{F_{0|T=1}(k)}{f_{0|T=1}(k)} \cdot \ln\left(\frac{u}{F_{0|T=1}(k)}\right) \leq Q_{0|T=1}(u) - k \leq -\frac{1 - F_{0|T=1}(k)}{f_{0|T=1}(k)} \cdot \ln\left(\frac{1 - u}{1 - F_{0|T=1}(k)}\right)$$

And similarly for  $Y_1$ , letting  $v = F_{1|T=1}(k-t)$ :

$$\frac{1 - F_{1|T=1}(k)}{f_{1|T=1}(k)} \cdot \ln\left(\frac{1 - v}{1 - F_{1|T=1}(k)}\right) \leq k - Q_{1|T=1}(v) \leq -\frac{F_{1|T=1}(k)}{f_{1|T=1}(k)} \cdot \ln\left(\frac{v}{F_{1|T=1}(k)}\right)$$

By RANK, we have that  $Y_i = k \iff F_{0|T=1}(Y_{0i}) \in [F_{0|T=1}(k), F_{0|T=1}(k) + \mathcal{B}^*] \iff F_{1|T=1}(Y_{1i}) \in [F_{1|T=1}(k) - \mathcal{B}^*, F_{1|T=1}(k)]$  where  $\mathcal{B}^* := P(Y_i = k|T = 1)$ , and thus:

$$E[Y_{0i} - Y_{1i}|Y_i = k, T_i = 0] = \frac{1}{\mathcal{B}^*} \int_{F_{0|T=1}(k)}^{F_{0|T=1}(k) + \mathcal{B}^*} \{Q_{0|T=1}(u) - k\} du + \frac{1}{\mathcal{B}^*} \int_{F_{1|T=1}(k) - \mathcal{B}^*}^{F_{1|T=1}(k)} \{k - Q_{1|T=1}(v)\} dv$$

A lower bound for  $E[Y_{0i} - Y_{1i}|Y_i = k, T_i = 0]$  is thus:

$$\begin{aligned} & \frac{F_{0|T=1}(k)}{f_{0|T=1}(k)(\mathcal{B}^*)} \int_{F_{0|T=1}(k)}^{F_{0|T=1}(k) + \mathcal{B}^*} \ln\left(\frac{u}{F_{0|T=1}(k)}\right) du + \frac{1 - F_{1|T=1}(k)}{f_{1|T=1}(k)(\mathcal{B}^*)} \int_{F_{1|T=1}(k) - \mathcal{B}^*}^{F_{1|T=1}(k)} \ln\left(\frac{1 - v}{1 - F_{1|T=1}(k)}\right) dv \\ & = g(F_{0|T=1}(k), f_{0|T=1}(k), \mathcal{B}^*) + h(F_{1|T=1}(k), f_{1|T=1}(k), \mathcal{B}^*) \end{aligned}$$

where as in Theorem 1:  $g(a, b, x) = \frac{a}{bx} (a + x) \ln(1 + \frac{x}{a}) - \frac{a}{b}$  and  $h(a, b, x) = g(1 - a, b, x)$ .

Similarly, an upper bound is:

$$\begin{aligned} & -\frac{1 - F_{0|T=1}(k)}{f_{0|T=1}(k)(\mathcal{B}^*)} \int_{F_{0|T=1}(k)}^{F_{0|T=1}(k) + \mathcal{B}^*} \ln\left(\frac{1 - u}{1 - F_{0|T=1}(k)}\right) du \\ & \quad - \frac{F_{1|T=1}(k)}{f_{1|T=1}(k)(\mathcal{B}^*)} \int_{F_{1|T=1}(k) - \mathcal{B}^*}^{F_{1|T=1}(k)} \ln\left(\frac{v}{F_{1|T=1}(k)}\right) dv \\ & = \tilde{g}(F_{0|T=1}(k), f_{0|T=1}(k), \mathcal{B}^*) + \tilde{h}(F_{1|T=1}(k), f_{1|T=1}(k), \mathcal{B}^*) \end{aligned}$$

where again  $\tilde{g}(a, b, x) = -g(1 - a, b, -x)$  and  $\tilde{h}(a, b, x) = -g(a, b, -x)$ . We have then that  $E[Y_{0i} - Y_{1i}|Y_i = k, T_i = 0] \in [\Delta_k^L, \Delta_k^U]$ , where:

$$\begin{aligned} \Delta_k^L & = g(F_{0|T=1}(k), f_{0|T=1}(k), \mathcal{B}^*) + g(1 - F_{1|T=1}(k), f_{1|T=1}(k), \mathcal{B}^*) \\ & = g(P(Y_{0i} \leq k \text{ and } T_i = 1), P(T_i = 1)f_{0|T=1}(k), P(Y_i = k \text{ and } T_i = 1)) \\ & \quad + g(P(Y_{1i} > k \text{ and } T_i = 1), P(T_i = 1)f_{1|T=1}(k), P(Y_i = k \text{ and } T_i = 1)) \end{aligned}$$

$$\begin{aligned}
\Delta_k^U &= -g(1 - F_{0|T=1}(k), f_{0|T=1}(k), -\mathcal{B}^*) - g(F_{1|T=1}(k), f_{1|T=1}(k), -\mathcal{B}^*) \\
&= -g(P(Y_{0i} > k \text{ and } T_i = 1), P(T_i = 1)f_{0|T=1}(k), -P(Y_i = k \text{ and } T_i = 1)) \\
&\quad - g(P(Y_{1i} \leq k \text{ and } T_i = 1), P(T_i = 1)f_{1|T=1}(k), -P(Y_i = k \text{ and } T_i = 1))
\end{aligned}$$

where I've used that the function  $g(a, b, x)$  is homogeneous of degree zero and multiplied each argument by  $P(T_i = 1)$ . The bounds are sharp as CHOICE, CONVEX and RANK imply no further restrictions on the marginal potential outcome distributions.

Next, note that:

$$\begin{aligned}
\lim_{y \uparrow k} f(y) &= \lim_{y \uparrow k} \frac{d}{dy} P(Y_{0i} \leq y \text{ and } W_i = 0) = \lim_{y \uparrow k} \frac{d}{dy} P(Y_{0i} \leq y \text{ and } W_i = 0 \text{ and } K_i^* = 0) \\
&= P(T_i = 1) \cdot \lim_{y \uparrow k} \frac{d}{dy} P(Y_{0i} \leq y | T_i = 1) = P(T_i = 1) \cdot f_{0|T=1}(k)
\end{aligned}$$

$$\begin{aligned}
\lim_{y \downarrow k} f(y) &= -\lim_{y \downarrow k} \frac{d}{dy} P(Y_{1i} \geq y \text{ and } W_i = 0) = -\lim_{y \downarrow k} \frac{d}{dy} P(Y_{1i} \geq y \text{ and } W_i = 0 \text{ and } K_i^* = 0) \\
&= P(T_i = 1) \cdot -\lim_{y \downarrow k} \frac{d}{dy} P(Y_{1i} \geq y | T_i = 1) = P(T_i = 1) \cdot f_{1|T=1}(k)
\end{aligned}$$

$$\mathcal{B}-p = P(Y_i = k \text{ and } K_i^* = 0) = P(Y_i = k \text{ and } K_i^* = 0 \text{ and } W_i = 0) = P(Y_i = k \text{ and } T_i = 1)$$

As shown by Dümbgen et al., 2017, BLC implies the existence of a continuous density function, which assures that these density limits exist and are equal to the corresponding potential outcome densities above. Thus, the quantities  $P(Y_i = k \text{ and } T_i = 1)$ ,  $P(T_i = 1) \cdot f_{0|T=1}(k)$  and  $P(T_i = 1) \cdot f_{1|T=1}(k)$  are all point-identified from the data.

Now we turn to the CDF arguments of  $\Delta_k^L$  and  $\Delta_k^U$ . Note that the desired quantities can be written

- $P(Y_{0i} \leq k \text{ and } T_i = 1) = P(Y_{0i} < k \text{ and } T_i = 1) = P(Y_{0i} < k \text{ and } W_i = 0)$
- $P(Y_{1i} > k \text{ and } T_i = 1) = P(Y_{1i} > k \text{ and } W_i = 0)$
- $P(Y_{0i} > k \text{ and } T_i = 1) = P(Y_{0i} > k \text{ and } W_i = 0)$
- $P(Y_{1i} \leq k \text{ and } T_i = 1) = P(Y_{1i} < k \text{ and } T_i = 1) = P(Y_{1i} < k \text{ and } W_i = 0)$

Let

$$A := P(Y_{0i} < k \text{ and } Y_i = Y_{0i} \text{ and } W_i = 1) \quad \text{and} \quad B := P(Y_{1i} > k \text{ and } Y_i = Y_{1i} \text{ and } W_i = 1)$$

The desired quantities are related to observables via  $A$  and  $B$ :

- $P(Y_i < k) = P(Y_{0i} < k \text{ and } W_i = 0) + A$

- $P(Y_i > k) = P(Y_{1i} > k \text{ and } W_i = 0) + B$
- $P(Y_i \leq k) - p = P(Y_i \leq k \text{ and } K_i^* = 0) = P(Y_i \leq k \text{ and } T_i = 1) + A = P(Y_{1i} \leq k \text{ and } W_i = 0) + A$
- $P(Y_i \geq k) - p = P(Y_i \geq k \text{ and } K_i^* = 0) = P(Y_i \geq k \text{ and } T_i = 1) + B = P(Y_{0i} > k \text{ and } W_i = 0) + B$

The four CDF arguments appearing in  $\Delta_k^L$  and  $\Delta^U$  are thus identified up to the correction terms  $A$  and  $B$ . A simple sufficient condition for  $A = B = 0$  is that there are no worker-choosers.

## J.6 Proof of Proposition H.1

The first order conditions with respect to  $z$  and  $h$  are:

$$\lambda F_L(L, K)e(h) = \phi + \frac{\beta_Y(z, h) + 1}{\beta_Y(z, h)} z$$

and

$$\lambda F_L(L, K)e(h)(\eta(h)/\beta_h(z, h) + 1) = z + \phi$$

where  $L = N(z, h)e(h)$ ,  $\eta(h) := e'(h)h/e(h)$ ,  $\beta_h(z, h) := N_h(z, h)h/N(z, h)$  and  $\beta_z(z, h) := N_z(z, h)Y/N(z, h)$  are elasticity functions and  $\lambda$  is a Lagrange multiplier. I have assumed that the functions  $|\beta_h|$ ,  $\beta_h$ , and  $\eta$  are strictly positive and finite globally. Combining the two equations, we have that an interior solution must satisfy either:  $z = \frac{\phi \frac{\eta}{\beta_h}}{1 - \frac{\beta_z + 1}{\beta_z} \frac{\beta_h + \eta}{\beta_h}}$  (Case 1), or that the denominator of the above is zero:  $\frac{\beta_h}{\beta_h + \eta} = \frac{\beta_z + 1}{\beta_z}$  (Case 2), where the dependence of  $\beta_z$  and  $\beta_h$  has been left implicit. Defining  $\beta(z, h) = |\beta_h(z, h)|/(\beta_z(z, h) + 1)$ , we can rewrite the condition for Case 2 as  $\beta(z, h) = \eta(h)$ .

With  $\phi = 0$ , we must be in Case 2 for any  $z > 0$  to have positive profits, and not that positivity of  $z$  requires  $\beta < \eta$  in case one. On the other hand if  $\phi > 0$  we cannot have Case 1 provided that  $\eta/\beta_h > 0$ . Now specialize to the conditions set out in the Proposition: that  $F_L = 1$ ,  $\lambda = 1$  (profit maximization), and  $\beta_h$ ,  $\beta_z$  and  $\eta$  are all constants. Then  $z = \frac{\phi \frac{\eta}{\beta_h}}{1 - \frac{\beta_z + 1}{\beta_z} \frac{\beta_h + \eta}{\beta_h}} = \phi \cdot \frac{\beta_z}{\beta_z + 1}$  and the first order condition for hours becomes

$$e(h) = \phi + \phi \frac{\eta}{\beta - \eta}$$

which simplifies to  $h = \left[ \frac{\phi}{e_0} \cdot \frac{\beta}{\beta - \eta} \right]^{1/\eta}$ .

## J.7 Proof of Proposition I.1

By constant treatment effects,  $f_1^G(y) = f_0^G(y + \delta)$  and note that both  $f_0^G(k)$  and  $f_1^G(k)$  are identified from the data. These can be transformed into densities for  $Y_{0i}$  and  $Y_{1i}$  via  $f_d(y) = G'(y)f_d^G(G(y))$  for  $d \in \{0, 1\}$ . With  $f_0(y)$  linear on the interval  $[k, k + \Delta]$ , the integral  $\int_k^{k+\Delta} f_0(y)dy$  evaluates to  $\mathcal{B} = \frac{\Delta}{2} (f_0(k) + f_0(k + \Delta))$ . Although  $f_0(k) = \lim_{y \uparrow k} f(y)$  by CONT,  $f_0(k + \Delta)$  is not immediately observable. However:

$$f_0(k + \Delta) = f_0(G^{-1}(G(k) + \delta)) = G'(k + \Delta)f_0^G(G(k) + \delta)$$

and furthermore by constant treatment effects:

$$f_0^G(G(k) + \delta) = f_1^G(G(k)) = (G'(k))^{-1}f_1(k) = (G'(k))^{-1}\lim_{y \downarrow k} f(y)$$

Combining these equations, we have the result.

## J.8 Proof of Proposition I.2

We seek a  $\Delta$  such that for some  $\theta_0$ :

$$\mathcal{B} = \int_{\tilde{k}}^{k+\Delta} g(y; \theta_0)dy \quad (19)$$

and

$$f(y) = \begin{cases} g(y; \theta_0) & y < k \\ g(y + \Delta; \theta_0) & y > k \end{cases} \quad (20)$$

and

$$g(y; \theta_0) > 0 \text{ for all } y \in [k, k + \Delta] \quad (21)$$

Recall from Equation (12) that  $\Delta = G^{-1}(G(k) + \delta) - k$  and hence  $\delta = G(k + \Delta) - G(k)$ . Thus if we find a unique  $\Delta$  satisfying the two equations, we have found a unique value of  $\delta$ : the true value of the homogenous effect  $\delta^G$ .

Suppose we have two candidate values  $\Delta' > \Delta$ . For them to both satisfy (19), we would need  $\Delta' = \Delta(\theta')$  and  $\Delta = \Delta(\theta)$  for  $\theta, \theta' \in \Theta$ , where  $\Delta(\theta)$  is the  $\Delta$  that satisfies Eq. (19) for a given  $\theta$ , (which is unique for each permissible value of  $\theta$  since  $g(y; \theta_0) > 0$ ). To satisfy (20), we would also need

$$g(y; \theta) = \begin{cases} f(y) & y < k \\ f(y - \Delta(\theta)) & y > k + \Delta(\theta) \end{cases} \quad g(y; \theta') = \begin{cases} f(y) & y < k \\ f(y - \Delta(\theta')) & y > k + \Delta(\theta') \end{cases} \quad (22)$$

Since  $g(y; \theta)$  is a real analytic function for any  $\theta \in \Theta$ , the function  $h_{\theta\theta'}(y) := g(y; \theta) - g(y; \theta')$  is real analytic. An implication of this is that if  $h_{\theta\theta'}(y)$  vanishes on the interval  $[0, \tilde{k}]$ , as it must by Equation (22), it must vanish everywhere on  $\mathbb{R}$ . Thus for any  $y > k + \Delta(\theta)$ :

$$g(y + \Delta(\theta') - \Delta(\theta); \theta) = g(y + \Delta(\theta') - \Delta(\theta); \theta') = g(y; \theta)$$

So  $g(y; \theta)$  is periodic with period  $\Delta(\theta') - \Delta(\theta)$ . Since  $g$  is non-negative, it cannot integrate to unity globally, and thus cannot be the same function as  $f_0(y)$ .

## J.9 Details of calculations for policy estimates

### J.9.1 Ex-post evaluation of time-and-a-half after 40

$$\mathbb{E}[Y_{0i} - Y_i] = (\mathcal{B} - p)\mathbb{E}[Y_{0i} - k | Y_i = k, K_i^* = 0] + p \cdot 0 + P(Y_{1i} > k)\mathbb{E}[Y_{0i} - Y_{1i} | Y_i > k]$$

Consider the first term

$$(\mathcal{B} - p)E[Y_{0i} - k | Y_i = k, K_i^* = 0] = (1 - p)\mathcal{B}^* \cdot \frac{1}{\mathcal{B}^*} \int_{F_{0|K^*=0}(k)}^{F_{0|K^*=0}(k) + \mathcal{B}^*} \{Q_{0|K^*=0}(u) - k\} du$$

where  $\mathcal{B}^* := P(Y_i = k | K^* = 0) = \frac{\mathcal{B} - p}{1 - p}$ . Bounds for the rightmost quantity are given by bi-log-concavity of  $Y_{0i}$ , just as in Theorem 1. In particular:

$$\begin{aligned} (\mathcal{B} - p)E[Y_{0i} - k | Y_i = k, K_i^* = 0] &\geq (1 - p)\mathcal{B}^* \cdot \frac{F_{0|K^*=0}(k)}{f_{0|K^*=0}(k)(\mathcal{B}^*)} \int_{F_{0|K^*=0}(k)}^{F_{0|K^*=0}(k) + \mathcal{B}^*} \ln \left( \frac{u}{F_{0|K^*=0}(k)} \right) du \\ &= (1 - p)\mathcal{B}^* \cdot g(F_{0|K^*=0}(k), f_{0|K^*=0}(k), \mathcal{B}^*) \\ &= (\mathcal{B} - p) \cdot g(F_-, f_-, \mathcal{B} - p) \end{aligned}$$

and

$$\begin{aligned} (\mathcal{B} - p)E[Y_{0i} - k | Y_i = k, K_i^* = 0] &\leq -(1 - p)\mathcal{B}^* \cdot \frac{1 - F_{0|K^*=0}(k)}{f_{0|K^*=0}(k)(\mathcal{B}^*)} \int_{F_{0|K^*=0}(k)}^{F_{0|K^*=0}(k) + \mathcal{B}^*} \ln \left( \frac{1 - u}{1 - F_{0|K^*=0}(k)} \right) du \\ &= (1 - p)\mathcal{B}^* \cdot g'(F_{0|K^*=0}(k), f_{0|K^*=0}(k), \mathcal{B}^*) \\ &= -(\mathcal{B} - p) \cdot g(1 - p - F_-, f_+, p - \mathcal{B}) \end{aligned}$$

where as before  $g(a, b, x) = \frac{a}{bx} (a + x) \ln \left( 1 + \frac{x}{a} \right) - \frac{a}{b}$  and  $g'(a, b, x) = -g(1 - a, b, -x)$ .

Now consider the second term of  $\mathbb{E}[Y_{0i} - Y_i]$ :  $P(Y_{1i} > k)\mathbb{E}[Y_{0i} - Y_{1i} | Y_i > k]$ . Taking as a lower bound an assumption of constant treatment effects in levels:  $P(Y_{1i} > k)\mathbb{E}[Y_{0i} - Y_{1i} | Y_i > k] \geq P(Y_{1i} > k)\Delta_k^L$ .

For an upper bound, we assume that  $\mathbb{E} \left[ \frac{dY_i(\rho)}{d\rho} \frac{\rho}{Y_i(\rho)} \middle| Y_i(\rho') = y, K_i^* = 0 \right] = \mathcal{E}$  for all  $\rho, \rho'$  and  $y$ . Consider then the buncher ATE in logs:

$$\begin{aligned} \mathbb{E} [\ln Y_{0i} - \ln Y_{1i} | Y_i = k, K_i^* = 0] &= \mathbb{E} [\ln Y_{0i} - \ln Y_{1i} | Y_{0i} \in [k, Q_{0|K^*=0}(F_{1|K^*=0})], K_i^* = 0] \\ &= \int_{\rho_0}^{\rho_1} d\rho \cdot \mathbb{E} \left[ \frac{dY_i(\rho)}{d\rho} \frac{1}{Y_i(\rho)} \middle| Y_{0i} \in [k, k + \Delta_0^*], K_i^* = 0 \right] \\ &= \int_{\rho_0}^{\rho_1} d \ln \rho \cdot \frac{1}{\mathcal{B}^*} \int_k^{k + \Delta_0^*} dy \cdot f_0(y) \cdot \mathbb{E} \left[ \frac{dY_i(\rho)}{d\rho} \frac{\rho}{Y_i(\rho)} \middle| Y_{0i} = y, K_i^* = 0 \right] \\ &= \mathcal{E} \int_{\rho_0}^{\rho_1} d \ln \rho = \mathcal{E} \ln(\rho_1 / \rho_0) \end{aligned} \tag{23}$$

with the notation that  $\Delta_0^* := Q_{0|K^*=0}(F_{1|K^*=0}) - k$ . Moreover:

$$\begin{aligned}\mathbb{E}[Y_{0i} - Y_{1i}|Y_i > k] &= \int_{\rho_0}^{\rho_1} d\rho \cdot \mathbb{E} \left[ \frac{dY_i(\rho)}{d\rho} \middle| Y_{1i} > k, K_i^* = 0 \right] \\ &= P(Y_{1i} > k)^{-1} \int_{\rho_0}^{\rho_1} d \ln \rho \cdot \int_k^\infty y \cdot f_1(y) \cdot \mathbb{E} \left[ \frac{dY_i(\rho)}{d\rho} \frac{\rho}{Y_i(\rho)} \middle| Y_{1i} = y, K_i^* = 0 \right] dy \\ &= \mathcal{E} \cdot \mathbb{E}[Y_{1i}|Y_{1i} > k] \int_{\rho_0}^{\rho_1} d \ln \rho = \mathcal{E} \ln(\rho_1/\rho_0) \cdot \mathbb{E}[Y_{1i}|Y_{1i} > k]\end{aligned}$$

Thus in the isoelastic model

$$E[Y_{0i} - Y_i] = (\mathcal{B} - p)E[Y_{0i} - k|Y_i = k, K_i^* = 0] + \mathbb{E}[Y_{1i}|Y_{1i} > k] \cdot P(Y_{1i} > k) \mathbb{E}[\ln Y_{0i} - \ln Y_{1i}|Y_i = k, K_i^* = 0]$$

and an upper bound is

$$\delta_k^U \cdot E[Y_i|Y_i > k] - (\mathcal{B} - p) \cdot g(1 - p - F_-, f_+, p - \mathcal{B})$$

where  $\delta_k^U$  is an upper bound to the buncher ATE in logs  $\mathbb{E}[\ln Y_{0i} - \ln Y_{1i}|Y_i = k, K_i^* = 0]$ .

### J.9.2 Moving to double time

I make use of the first step deriving the expression for  $\partial_{\rho_1} E[Y_i^{[k, \rho_1]}]$  in Theorem 2, namely that:

$$\partial_{\rho_1} E[Y_i^{[k, \rho_1]}] = k \partial_{\rho_1} \mathcal{B}^{[k, \rho_1]} + \partial_{\rho_1} \{P(Y_i(\rho_1) > k) \mathbb{E}[Y_i(\rho_1)|Y_i(\rho_1) > k]\}$$

Thus:

$$\begin{aligned}E[Y_i^{[k, \rho_1]}] - E[Y_i^{[k, \bar{\rho}_1]}] &= - \int_{\rho_1}^{\bar{\rho}_1} \partial_\rho E[Y_i^{[k, \rho]}] d\rho = - \int_{\rho_1}^{\bar{\rho}_1} \left\{ k \partial_\rho \mathcal{B}^{[k, \rho]} + \partial_\rho \{P(Y_i(\rho) > k) \mathbb{E}[Y_i(\rho)|Y_i(\rho) > k]\} \right\} d\rho \\ &= -k(\mathcal{B}^{[k, \bar{\rho}_1]} - \mathcal{B}^{[k, \rho_1]}) + P(Y_i(\rho_1) > k) \mathbb{E}[Y_i(\rho_1)|Y_i(\rho_1) > k] - P(Y_i(\bar{\rho}_1) > k) \mathbb{E}[Y_i(\bar{\rho}_1)|Y_i(\bar{\rho}_1) > k] \\ &= -k(\mathcal{B}^{[k, \bar{\rho}_1]} - \mathcal{B}^{[k, \rho_1]}) + \{P(Y_i(\rho_1) > k) - P(Y_i(\bar{\rho}_1) > k)\} \cdot \mathbb{E}[Y_i(\bar{\rho}_1)|Y_i(\bar{\rho}_1) > k] \\ &\quad + P(Y_i(\rho_1) > k) (\mathbb{E}[Y_i(\rho_1)|Y_i(\rho_1) > k] - \mathbb{E}[Y_i(\bar{\rho}_1)|Y_i(\bar{\rho}_1) > k]) \\ &= (\mathbb{E}[Y_{1i}|Y_{1i} > k] - k) (\mathcal{B}^{[k, \bar{\rho}_1]} - \mathcal{B}^{[k, \rho_1]}) + P(Y_{1i} > k) (\mathbb{E}[Y_{1i}|Y_{1i} > k] - \mathbb{E}[Y_i(\bar{\rho}_1)|Y_i(\bar{\rho}_1) > k]) \\ &\leq (\mathbb{E}[Y_i(\bar{\rho}_1)|Y_i(\bar{\rho}_1) > k] - k) (\mathcal{B}^{[k, \bar{\rho}_1]} - \mathcal{B}^{[k, \rho_1]}) + P(Y_{1i} > k) \mathbb{E}[Y_i(\rho_1) - Y_i(\bar{\rho}_1)|Y_{1i} > k] \\ &\leq (\mathbb{E}[Y_i(\bar{\rho}_1)|Y_i(\bar{\rho}_1) > k] - k) (\mathcal{B}^{[k, \rho_1]} - p) + P(Y_{1i} > k) \mathbb{E}[Y_i(\rho_1) - Y_i(\bar{\rho}_1)|Y_{1i} > k] \\ &\leq (\mathbb{E}[Y_i(\bar{\rho}_1)|Y_i(\bar{\rho}_1) > k] - k) (\mathcal{B}^{[k, \rho_1]} - p) + P(Y_{1i} > k) \mathbb{E}[Y_{0i} - Y_{1i}|Y_{1i} > k] \\ &\approx (\mathbb{E}[Y_{1i}|Y_{1i} > k] - k) (\mathcal{B}^{[k, \rho_1]} - p) + P(Y_{1i} > k) \mathbb{E}[Y_{0i} - Y_{1i}|Y_{1i} > k] \\ &\leq (\mathbb{E}[Y_{1i}|Y_{1i} > k] - k) (\mathcal{B}^{[k, \rho_1]} - p) + P(Y_{1i} > k) E[Y_i|Y_i > k] \cdot \delta_k^U\end{aligned}$$

In the iso-elastic model, making use instead of the final expression for  $\partial_{\rho_1} E[Y_i^{[k, \rho_1]}]$  in Thm. 2:

$$\begin{aligned}
E[Y_i^{[k, \rho_1]}] - E[Y_i^{[k, \bar{\rho}_1]}] &= - \int_{\rho_1}^{\bar{\rho}_1} \partial_{\rho} E[Y_i^{[k, \rho_1]}] d\rho = \int_{\rho_1}^{\bar{\rho}_1} d\rho \int_k^{\infty} f_{\rho}(y) \mathbb{E} \left[ \frac{dY_i(\rho)}{d\rho} \middle| Y_i(\rho) = y \right] dy \\
&= \int_{\rho_1}^{\bar{\rho}_1} d \ln \rho \int_k^{\infty} f_{\rho}(y) y \cdot \mathbb{E} \left[ \frac{dY_i(\rho)}{d\rho} \frac{\rho}{Y_i(\rho)} \middle| Y_i(\rho) = y \right] dy \\
&\geq \mathcal{E} \int_{\rho_1}^{\bar{\rho}_1} d \ln \rho \int_k^{\infty} f_{\rho}(y) y \cdot dy = \mathcal{E} \int_{\rho_1}^{\bar{\rho}_1} d \ln \rho \cdot P(Y_i(\rho) > k) \mathbb{E}[Y_i(\rho) | Y_i(\rho) > k] \\
&\geq \mathcal{E} \ln(\bar{\rho}_1 / \rho_1) \cdot P(Y_i(\bar{\rho}_1) > k) \mathbb{E}[Y_i(\bar{\rho}_1) | Y_i(\bar{\rho}_1) > k] \\
&= \mathcal{E} \ln(\bar{\rho}_1 / \rho_1) \cdot \{P(Y_{1i} > k) \mathbb{E}[Y_{1i} | Y_{1i} > k] + (P(Y_i(\bar{\rho}_1) > k) \mathbb{E}[Y_i(\bar{\rho}_1) | Y_i(\bar{\rho}_1) > k] - P(Y_{1i} > k) \mathbb{E}[Y_{1i} | Y_{1i} > k])\} \\
&= \mathcal{E} \ln(\bar{\rho}_1 / \rho_1) \cdot \left\{ P(Y_{1i} > k) \mathbb{E}[Y_{1i} | Y_{1i} > k] - \left( E[Y_i^{[k, \rho_1]}] - E[Y_i^{[k, \bar{\rho}_1]}] \right) + k(\mathcal{B}^{[k, \bar{\rho}_1]} - \mathcal{B}^{[k, \rho_1]}) \right\}
\end{aligned}$$

where in the fourth step I've used that  $Y_i(\rho)$  is decreasing in  $\rho$  with probability one, which follows from SEPARABLE and CONVEX. So:

$$\begin{aligned}
E[Y_i^{[k, \rho_1]}] - E[Y_i^{[k, \bar{\rho}_1]}] &\geq \frac{\mathcal{E} \ln(\bar{\rho}_1 / \rho_1)}{1 + \mathcal{E} \ln(\bar{\rho}_1 / \rho_1)} \cdot \{P(Y_{1i} > k) \mathbb{E}[Y_{1i} | Y_{1i} > k] + k(\mathcal{B}^{[k, \bar{\rho}_1]} - \mathcal{B}^{[k, \rho_1]})\} \\
&\geq \frac{\mathcal{E} \ln(\bar{\rho}_1 / \rho_1)}{1 + \mathcal{E} \ln(\bar{\rho}_1 / \rho_1)} \cdot P(Y_{1i} > k) \mathbb{E}[Y_{1i} | Y_{1i} > k]
\end{aligned}$$

### J.9.3 Effect of a change to the kink point on bunching

Using that  $p(k^*) = p$  and  $p(k') = 0$ :

$$\begin{aligned}
\mathcal{B}^{[k', \rho_1]} - \mathcal{B}^{[k^*, \rho_1]} &= \left( \mathcal{B}^{[k', \rho_1]} - p(k') \right) - \left( \mathcal{B}^{[k^*, \rho_1]} - p(k^*) \right) - p = -p + \int_{k^*}^{k'} dk \cdot \partial_k \left( \mathcal{B}^{[k', \rho_1]} - p(k) \right) \\
&= -p + \int_{k^*}^{k'} dk \cdot (f_1(k) - f_0(k)) = -p + F_1(k') - F_1(k^*) - F_0(k') + F_0(k^*) \\
&= P(k^* < Y_{1i} \leq k') - P(k^* < Y_{0i} \leq k') - p \\
&= P(k^* < Y_i \leq k') - P(k^* < Y_{0i} \leq k') - p
\end{aligned}$$

if  $k' > k^*$ . Similarly, if  $k' < k^*$ :

$$\mathcal{B}^{[k', \rho_1]} - \mathcal{B}^{[k^*, \rho_1]} = P(k' \leq Y_{0i} < k^*) - P(k' \leq Y_{1i} < k^*) - p = P(k' \leq Y_i < k^*) - P(k' \leq Y_{1i} < k^*) - p$$

The lemma in the next section gives identified bounds on the counterfactual quantity that appears in the expression in each case.

#### J.9.4 Average effect of a change to the kink point on hours

$$\begin{aligned}
E[Y_i^{[k', \rho_1]}] - E[Y_i^{[k^*, \rho_1]}] &= \int_{k^*}^{k'} \partial_k E[Y_i^{[k, \rho_1]}] dk = \int_{k^*}^{k'} \{\mathcal{B}^{[k, \rho_1]} - p(k)\} dk \\
&= k (\mathcal{B}^{[k, \rho_1]} - p(k)) \Big|_{k^*}^{k'} - \int_{k^*}^{k'} k \cdot \partial_k \{\mathcal{B}^{[k, \rho_1]} - p(k)\} dk \\
&= k' \mathcal{B}^{[k', \rho_1]} - k^* (\mathcal{B} - p) - \int_{k^*}^{k'} y (f_1(y) - f_0(y)) dy \\
&= (k' - k^*) \mathcal{B}^{[k', \rho_1]} + k^* (\mathcal{B}^{[k', \rho_1]} - \mathcal{B}) + pk^* - \int_{k^*}^{k'} y (f_1(y) - f_0(y)) dy
\end{aligned}$$

For  $k' > k^*$ , this is equal to

$$\begin{aligned}
&(k' - k^*) \mathcal{B}^{[k', \rho_1]} + k^* (\mathcal{B}^{[k', \rho_1]} - (\mathcal{B} - k)) + P(k^* < Y_{0i} \leq k') (\mathbb{E}[Y_{0i} | k^* < Y_{0i} \leq k'] - P(k^* < Y_{1i} \leq k')) (\mathbb{E}[Y_{1i} | k^* < Y_{1i} \leq k'] - k^*) \\
&= (k' - k^*) \mathcal{B}^{[k', \rho_1]} + P(k^* < Y_{0i} \leq k') (\mathbb{E}[Y_{0i} | k^* < Y_{0i} \leq k'] - k^*) - P(k^* < Y_{1i} \leq k') (\mathbb{E}[Y_{1i} | k^* < Y_{1i} \leq k'] - k^*) \\
&= (k' - k^*) \mathcal{B}^{[k', \rho_1]} + P(k^* < Y_{0i} \leq k') (\mathbb{E}[Y_{0i} | k^* < Y_{0i} \leq k'] - k^*) - P(k^* < Y_i \leq k') (\mathbb{E}[Y_i | k^* < Y_i \leq k'] - k^*)
\end{aligned}$$

The first term represents the mechanical effect from the bunching mass under  $k'$  being transported from  $k^*$  to  $k'$ , and can be bounded given the bounds for  $\mathcal{B}^{[k', \rho_1]} - \mathcal{B}^{[k^*, \rho_1]}$  in the last section. The last term is point identified from the data, while the middle term can be bounded using bi-log concavity of  $Y_{0i}$  conditional on  $K^* = 0$ . Similarly, when  $k' < k^*$ , the effect on hours is:

$$\begin{aligned}
&(k' - k^*) \mathcal{B}^{[k', \rho_1]} + P(k' \leq Y_{0i} < k^*) (k^* - \mathbb{E}[Y_{0i} | k' \leq Y_{0i} < k^*]) - P(k' \leq Y_{1i} < k^*) (k^* - \mathbb{E}[Y_{1i} | k' \leq Y_{1i} < k^*]) \\
&= (k' - k^*) \mathcal{B}^{[k', \rho_1]} + P(k' \leq Y_i < k^*) (k^* - \mathbb{E}[Y_i | k' \leq Y_i < k^*]) - P(k' \leq Y_{1i} < k^*) (k^* - \mathbb{E}[Y_{1i} | k' \leq Y_{1i} < k^*])
\end{aligned}$$

with the middle term point identified from the data and last term bounded by bi-log concavity of  $Y_{1i}$  conditional on  $K^* = 0$ . The analytic bounds implied by BLC in each case are given by the Lemma below.

**Lemma.** Suppose  $Y_i$  is a bi-log concave random variable with CDF  $F(y)$ . Let  $F_0 := F(y_0)$  and  $f_0 = f(y_0)$  be the CDF and density, respectively, evaluated at a fixed  $y_0$ . Then, for any  $y' > y_0$ :

$$A \leq P(y_0 \leq Y_i \leq y') (\mathbb{E}[Y_i | y_0 \leq Y_i \leq y'] - y_0) \leq B$$

and for any  $y' < y_0$ :

$$B \leq P(y' \leq Y_i \leq y_0) (y_0 - \mathbb{E}[Y_i | y' \leq Y_i \leq y_0]) \leq A$$

where  $A = g(F_0, f_0, F_L(y'))$  and  $B = g(1 - F_0, f_0, 1 - F_U(y'))$ , with

$$F_L(y') = 1 - (1 - F_0) e^{-\frac{f_0}{1-F_0}(y-y_0)}, \quad F_U(y') = F_0 e^{\frac{f_0}{F_0}(y'-y_0)}$$

and

$$g(a, b, c) = \begin{cases} \frac{ac}{b} \left( \ln \left( \frac{c}{a} \right) - 1 \right) + \frac{a^2}{b} & \text{if } c > 0 \\ \frac{a^2}{b} & \text{if } c \leq 0 \end{cases}$$

In either of the two cases  $\max\{0, F_L(y')\} \leq F(y') \leq \min\{1, F_U(y')\}$ .

*Proof.* As shown by Dümbgen et al., 2017, bi-log concavity of  $Y_i$  implies not only that  $f(y)$  exists, but that it is strictly positive, and we may then define a quantile function  $Q = F^{-1}$  such that  $Q(F(y)) = y$  and  $y = Q(F(y))$ . Theorem 1 of Dümbgen et al., 2017 also shows that for any  $y'$ :

$$\underbrace{1 - (1 - F_0)e^{-\frac{f_0}{1-F_0}(y-y_0)}}_{:=F_L(y')} \leq F(y') \leq \underbrace{F_0 e^{\frac{f_0}{F_0}(y'-y_0)}}_{:=F_U(y')}$$

We can re-express this as bounds on the quantile function evaluated at any  $u' \in [0, 1]$ :

$$\underbrace{y_0 + \frac{F_0}{f_0} \ln \left( \frac{u}{F_0} \right)}_{Q_L(u')} \leq Q(u') \leq \underbrace{y_0 - \frac{1 - F_0}{f_0} \ln \left( \frac{1 - u}{1 - F_0} \right)}_{Q_U(u')}$$

Write the quantity of interest as:

$$P(y_0 \leq Y_i \leq y') (\mathbb{E}[Y_i | y_0 \leq Y_i \leq y'] - y_0) = \int_{y_0}^{y'} (y - y_0) f(y) dy = \int_{F_0}^{F(y')} (Q(u) - y_0) du$$

Given that  $Q(u) \geq y_0$ , the integral is increasing in  $F(y')$ . Thus an upper bound is:

$$\begin{aligned} P(y_0 \leq Y_i \leq y') (\mathbb{E}[Y_i | y_0 \leq Y_i \leq y'] - y_0) &\leq \int_{F_0}^{F_U(y')} (Q_U(u) - y_0) du \\ &= -\frac{1 - F_0}{f_0} \int_{F_0}^{F_U(y')} \ln \left( \frac{1 - u}{1 - F_0} \right) du \\ &= \frac{(1 - F_0)^2}{f_0} \int_1^{\frac{1 - F_U(y')}{1 - F_0}} \ln(v) dv \\ &= \frac{(1 - F_0)(1 - F_U(y'))}{f_0} \left( \ln \left( \frac{1 - F_U(y')}{1 - F_0} \right) - 1 \right) + \frac{(1 - F_0)^2}{f_0} \end{aligned}$$

where we've made the substitution  $v = \frac{1-u}{1-F_0}$  and used that  $\int \ln(v) dv = v(\ln(v) - 1)$ . Inspection of the formulas for  $F_U$  and  $F_L$  reveal that  $F_U \in (0, \infty)$  and  $F_L \in (-\infty, 1)$ . In the event that  $F_U(y') \geq 1$ , the above expression is undefined but we can replace  $F_U(y')$  with one and still obtain valid bounds:

$$P(y_0 \leq Y_i \leq y') (\mathbb{E}[Y_i | y_0 \leq Y_i \leq y'] - y_0) \leq -\frac{(1 - F_0)^2}{f_0} \int_0^1 \ln(v) dv = \frac{(1 - F_0)^2}{f_0}$$

where we've used that  $\int_0^1 \ln(v) dv = -1$ .

Similarly, a lower bound is:

$$\begin{aligned} P(y_0 \leq Y_i \leq y') (\mathbb{E}[Y_i | y_0 \leq Y_i \leq y'] - y_0) &\geq \int_{F_0}^{F_L(y')} (Q_L(u) - y_0) du = \frac{F_0}{f_0} \int_{F_0}^{F_L(y')} \ln\left(\frac{u}{F_0}\right) du \\ &= \frac{F_0^2}{f_0} \int_1^{F_L(y')/F_0} \ln(v) dv \\ &= \frac{F_0 F_L(y')}{f_0} \left( \ln\left(\frac{F_L(y')}{F_0}\right) - 1 \right) + \frac{F_0^2}{f_0} \end{aligned}$$

where we've made the substitution  $v = \frac{u}{F_0}$ . If  $F_L(y') \leq 0$ , then we replace with zero to obtain

$$P(y_0 \leq Y_i \leq y') (\mathbb{E}[Y_i | y_0 \leq Y_i \leq y'] - y_0) \geq -\frac{F_0^2}{f_0} \int_0^1 1 \ln(v) dv = \frac{F_0^2}{f_0}$$

When  $y' < y$ , write the quantity of interest as:

$$P(y' \leq Y_i \leq y_0) (y_0 - \mathbb{E}[Y_i | y' \leq Y_i \leq y_0]) = \int_{y'}^{y_0} (y_0 - y) f(y) dy = \int_{F(y')}^{F_0} (y_0 - Q(u)) du$$

This integral is decreasing in  $F(y')$ , so an upper bound is:

$$\begin{aligned} P(y' \leq Y_i \leq y_0) (y_0 - \mathbb{E}[Y_i | y' \leq Y_i \leq y_0]) &\leq \int_{F_L(y')}^{F_0} (y_0 - Q_L(u)) du = -\frac{F_0}{f_0} \int_{F_L(y')}^{F_0} \ln\left(\frac{u}{F_0}\right) du \\ &= -\frac{F_0^2}{f_0} \int_{F_L(y')/F_0}^1 \ln(v) dv \\ &= \frac{F_0 F_L(y')}{f_0} \left( \ln\left(\frac{F_L(y')}{F_0}\right) - 1 \right) + \frac{F_0^2}{f_0} \end{aligned}$$

or simply  $F_0^2/f_0$  when  $F_L(y') \leq 0$ , and a lower bound is:

$$\begin{aligned} P(y' \leq Y_i \leq y_0) (y_0 - \mathbb{E}[Y_i | y' \leq Y_i \leq y_0]) &\geq \int_{F_U(y')}^{F_0} (y_0 - Q_U(u)) du \\ &= \frac{1 - F_0}{f_0} \int_{F_U(y')}^{F_0} \ln\left(\frac{1 - u}{1 - F_0}\right) du \\ &= -\frac{(1 - F_0)^2}{f_0} \int_{\frac{1 - F_U(y')}{1 - F_0}}^1 \ln(v) dv \\ &= \frac{(1 - F_0)(1 - F_U(y'))}{f_0} \left( \ln\left(\frac{1 - F_U(y')}{1 - F_0}\right) - 1 \right) + \frac{(1 - F_0)^2}{f_0} \end{aligned}$$

or simply  $(1 - F_0)^2/f_0$  when  $F_U(y') \geq 1$ .  $\square$

In estimation, I censor intermediate CDF bound estimates based on the above lemma at zero and one. These constraints are not typically binding so I ignore the effect of this on asymptotic normality of the final estimators, when constructing confidence intervals.

## J.10 Details of calculating wage correction terms

### For the ex-post effect of the kink

Suppose that straight-time wages  $w^*$  are set according to Equation (1) for all workers, where  $h^*$  are their anticipated hours. The straight-wages that would exist absent the FLSA  $w_0^*$ , yield the same total earnings  $z^*$ , so:

$$w_0^* h^* = w^* (h^* + (\rho_1 - 1)(h^* - k) \mathbb{1}(h^* > k))$$

where  $k = 40$  and  $\rho_1 = 1.5$ . The percentage change is thus

$$(w_0^* - w^*)/w^* = \frac{(\rho_1 - 1)(h^* - k) \mathbb{1}(h^* > k)}{h^* + (\rho_1 - 1)(h^* - k) \mathbb{1}(h^* > k)}$$

If  $h_{0i}$  is constant elasticity in the wage with elasticity  $\mathcal{E}$ , then we would expect

$$\frac{h_{0it} - h_{0it}^*}{h_{0it}} = 1 - \left( 1 + \frac{(\rho_1 - 1)(h^* - k) \mathbb{1}(h^* > k)}{h^* + (\rho_1 - 1)(h^* - k) \mathbb{1}(h^* > k)} \right)^\mathcal{E}$$

Taking  $h_{0it} \approx h_{1it} \approx h^*$  and integrating along the distribution of  $h_{1it}$ , we have:

$$\mathbb{E}[h_{0it} - h_{0it}^*] \approx \mathbb{E} \left[ \mathbb{1}(h_{it} > k) h_{it} \left( 1 - \left( 1 + \frac{(\rho_1 - 1)(h_{it} - k)}{h_{it} + (\rho_1 - 1)(h_{it} - k)} \right)^\mathcal{E} \right) \right]$$

which will be negative provided that  $\mathcal{E} < 0$ . The total ex-post effect of the kink is:

$$\mathbb{E}[h_{it} - h_{0it}^*] = \mathbb{E}[h_{it} - h_{0it}] + \mathbb{E}[h_{0it} - h_{0it}^*]$$

### For a move to double-time

The straight-wages  $w_2^*$  that would exist with double time, for workers with  $h^* > k$ , that yield the same total earnings  $z^*$  as the actual straight wages  $w^*$  satisfy:

$$w_2^* (k + (\bar{\rho}_1 - 1)(h^* - k)) = w^* (k + (\rho_1 - 1)(h^* - k))$$

where  $\bar{\rho}_1 = 2$ . The percentage change is thus

$$(w_2^* - w^*)/w^* = \frac{k + (\rho_1 - 1)(h^* - k)}{k + (\bar{\rho}_1 - 1)(h^* - k)} - 1$$

Let  $\bar{h}_{0i}$  be hours under a straight-time wage of  $w_2^*$ . By a similar calculation thus:

$$\mathbb{E}[\bar{h}_{it}^{[\bar{\rho}_1, k]} - h_{it}^{[\bar{\rho}_1, k]}] \approx \mathbb{E} \left[ \mathbb{1}(h_{it} > k) h_{it} \left( \left( \frac{k + (\rho_1 - 1)(h^* - k)}{k + (\bar{\rho}_1 - 1)(h^* - k)} \right)^\mathcal{E} - 1 \right) \right]$$

The total effect of a move to double-time is:

$$\mathbb{E}[\bar{h}_{it}^{[\bar{\rho}_1, k]} - h_{it}] = \mathbb{E}[\bar{h}_{it}^{[\bar{\rho}_1, k]} - h_{it}^{[\bar{\rho}_1, k]}] + \mathbb{E}[h_{it}^{[\bar{\rho}_1, k]} - h_{it}]$$

The above definitions are depicted visually in Figure 15 below.

**Figure 15:** Depiction of  $h^*$ ,  $h_0$ ,  $h_0^*$  and  $h_1$  for a single fixed worker that works overtime at  $h_1$  hours this week. Their realized wage  $w^*$  has been set to yield earnings  $z^*$  based on anticipated hours  $h^*$  given the FLSA kink. In a world without the FLSA, the worker’s wage would instead be  $w_0^* = z^*/h^*$ , and this week the firm would have chosen  $h_0^*$  hours, where the worker’s marginal productivity this week is  $w_0^*$  (in the benchmark model). *Note:* while  $(z^*, h^*)$  is chosen jointly with employment and on the basis of anticipated productivity, choice of  $h_0^*$  is instead constrained by the contracted purple pay schedule (with the worker already hired) and on the basis of updated productivity.  $h_1$  may differ from  $h^*$  for this same reason. In the numerical calculation  $h^*$  is approximated by  $h_1$  – which corresponds to productivity variation being small and  $h^*$  being a credible choice given the FLSA. If credibility (the firm not wanting to renege too far on hours after hiring) were a constraint on the choice of  $(z^*, h^*)$  in the no-FLSA counterfactual, then  $h^*$  would be smaller without the FLSA, but I consider this “second-order” and do not attempt a correction here.

### Changing the location of the kink

Let  $\mathcal{B}_w^{[k]}$  denote bunching with the kink at location  $k$  and (a distribution of) wages denoted by  $w$ . Then the effect of moving  $k$  on bunching is

$$\mathcal{B}_{w'}^{[k']} - \mathcal{B}_w^{[k^*]} = \left( \mathcal{B}_w^{[k']} - \mathcal{B}_w^{[k^*]} \right) + \left( \mathcal{B}_{w'}^{[k']} - \mathcal{B}_w^{[k']} \right)$$

where  $w'$  are the wages that would occur with bunching at the new kink point  $k'$ . The first term has been estimated by the methods described above, with the second term representing a correction due to wage adjustment. Taking  $Y_{0i} \approx Y_{1i} \approx h^*$ , the straight-time wages  $w^*$  set according to Equation (1) that would change are those between  $k'$  and  $k^*$ . Consider the case  $k' < k^*$ . We expect wages to fall, as the overtime policy becomes more stringent, and  $\left( \mathcal{B}_{w'}^{[k']} - \mathcal{B}_w^{[k']} \right)$  is only nonzero to the extent that the increase in  $Y_0$  and  $Y_1$  changes the mass of each in the range  $[k', k^*]$ . With the range  $[k', k^*]$  to the left of the mode of  $Y_{0i}$ , it is most

plausible that this mass will decrease. Similarly, for  $Y_{1i}$ , it is most likely that this mass will decrease, making the overall sign of  $(\mathcal{B}_{w'}^{[k']} - \mathcal{B}_w^{[k']})$  ambiguous. However, since most of the adjustment should occur for workers who are typically found between  $k$  and  $k'$ , we would not expect either term to be very different from zero.

Now consider the effect of average hours:

$$\mathbb{E}[Y_{w'}^{[k']} - Y_w^{[k*]}] = \mathbb{E}[Y_w^{[k']} - Y_w^{[k*]}] + \mathbb{E}[Y_{w'}^{[k']} - Y_w^{[k']}]$$

For a reduction in  $k$ , we would expect wages  $w'$  to be lower with  $k = k'$  and hence the second term positive. This will attenuate the effects that are bounded by the methods above, holding the wages fixed at their realized levels.

Consider first the case of  $k' < k^*$ . Let  $w'$  be wages under the new kink point  $k'$ , and assuming they adjust to keep total earnings  $z^*$  constant, wages  $w'$  will change if  $h^*$  is between  $k$  and  $k'$  as:  $w'(k' + 0.5(h^* - k')) = w^*h^*$ , and the percentage change for these workers is thus

$$(w' - w^*)/w^* = \frac{h^*}{k' + 0.5(h^* - k')} - 1$$

$$\mathbb{E}[Y_{w'}^{[k']} - Y_w^{[k']}] \approx \mathbb{E} \left[ \mathbb{1}(k' < Y_i < k^*) Y_i \left( \left( \frac{Y_i}{k' + 0.5(Y_i - k')} \right)^\varepsilon - 1 \right) \right]$$

In the case of  $k' > k^*$ , we will have wages change as:  $w'h^* = w^*(k^* + 0.5(h^* - k^*))$  if  $h^*$  is between  $k$  and  $k'$ . The percentage change for these workers is thus

$$(w' - w^*)/w^* = \frac{k^* + 0.5(h^* - k^*)}{h^*} - 1$$

$$\mathbb{E}[Y_{w'}^{[k']} - Y_w^{[k']}] \approx \mathbb{E} \left[ \mathbb{1}(k^* < Y_i < k') Y_i \left( \left( \frac{k^* + 0.5(Y_i - k^*)}{Y_i} \right)^\varepsilon - 1 \right) \right]$$
